When the scattered light level is very low, the photodetector output reveals the presence of the individual photon pulses. By correlating the actual photon pulses from a wide bandwidth photodetector, the photon correlator was designed to work in situations where the attainable signal intensity was very low (low SNR). However, as normally used, it could not provide the velocity of individual particles but only the averaged quantities, such as mean and turbulence intensities.

The “counter” type processor was developed next, and basically measured the time for a certain number (typically, eight) of cycles of the Doppler signal. Although it measured the velocity of individual particles, it depended on the careful setting of amplifier gain and, especially, threshold levels to discriminate between background noise and burst signals. Counters were the processors of choice for many years, and excellent measurements were obtained [42]. However, the reliance on user skill, the difficulty in handling low SNR signals, the possibility of getting erroneous measurements, the inclination to ignore signals from small particles, and the desire to make measurements close to surfaces and in complex flows led to the need for a better signal processor.

Digital Signal Processing

The latest development in signal processing is in the area of digital signal processors. Recent developments in high-speed digital signal processing now permit the use of these techniques to extract the frequency from individual Doppler bursts fast enough to actually follow the flow when the seeding concentration is adequate in a wide range of measurement situations. By digitizing the incoming signal and using the Fourier transform [43] or autocorrelation [44] algorithms, these new digital processors can work with lower SNR signals (than counters), while generally avoiding erroneous data outputs. While instruments using these techniques are certainly not new, standard instruments were not designed to make rapid individual measurements on the noisy, short-duration burst signals with varying amplitudes that are typical of Doppler bursts.

Because the flow velocity and hence the signal frequency varies from one burst to the next, the sampling rate needs to be varied accordingly. And because the signal frequency is not known \textit{a priori}, the ability to optimally sample the signal has been one of the most important challenges in digital signal processing. In one of the digital signal processors, the question of deciding the sample rate is addressed by a burst detector that uses SNR to identify the presence of a signal [44]. In addition, the burst detector provides the duration and an approximate estimate of the frequency of each of the burst signals. This frequency estimate is used to select the output of the sampler (from the many samplers) that had sampled the burst signal at the optimum rate. Besides optimizing the sample rate for each burst, the burst detector information is also used to focus on and process the middle portion of the burst where the SNR is maximum. These optimization schemes, followed by digital signal processing, provide an accurate digital output that is proportional to the signal frequency, and hence the fluid velocity.

Seeding and Other Aspects

The performance of an LDV system can be significantly improved by optimizing the source of the signal, the scattering particle. The first reaction of many experimentalists is to rely on the particles naturally present in the flow. There are a few situations (e.g., LDV systems operating in forward scatter to measure water or liquid flows) where the particles naturally present in the flow are sufficient in number and size to provide good signal quality and hence good measurements. In most flow measurement situations, particles are added to the flow (generally referred to as seeding the flow) to obtain an adequate number of suitable scatterers. Use of a proper particle can result in orders of magnitude increase in signal quality (SNR), and hence can have greater impact on signal quality than the modification of any other component in the LDV system. Ideally, the seed particles should be naturally buoyant in the fluid, provide adequate scattered light intensity, have large enough number concentration, and have uniform properties from particle to particle. While this ideal is difficult to achieve, adequate particle sources and distribution systems have been developed [29, 45–47].
LDV measurements of internal flows such as in channels, pipes and combustion chambers result in the laser beams (as well as the scattered light) going through transparent walls or “windows.” In many cases, the window is flat and, hence, the effect of light refraction can be a simple displacement of the measuring region. In the case of internal flows with curved walls, each beam can refract by different amounts and the location of the measuring region needs to be carefully estimated [48]. For internal flows in models with complex geometries, the beam access needs to be carefully selected so that the beams do cross inside. Further, to make measurements close to the wall in an internal flow, the refraction effect of the wall material on the beam path needs to be minimized. One of the approaches is to use a liquid [49] that has the same refractive index as that of the wall material.

Data Analysis
The flow velocity is “sampled” by the particle passing through the measuring volume, and the velocity measurement is obtained only when the Doppler signal, created by the particle, is processed and output as a data point by the signal processor. While averaging the measurements to get, for example, mean velocity would seem reasonable, this method gives the wrong answer. This arises from the fact that the number of particles going through the measuring region per unit time is higher at high velocities than at low velocities. In effect, there is a correlation between the measured quantity (velocity) and the sampling process (particle arrival). Hence, a simple average of the data points will bias the mean value (and other statistical parameters) toward the high-velocity end and is referred to as velocity bias [50]. The magnitude of the bias error depends on the magnitude of the velocity variations about the mean. If the variations in velocity are sufficiently small, the error might not be significant.

If the actual data rate is so high that the output data is essentially able to characterize the flow (time history), then the output can be sampled at uniform time increments. This is similar to the procedure normally used for sampling a continuous analog signal using an ADC. This will give the proper value for both the mean and the variance when the data rate is sufficiently high compared to the rates based on the Taylor microscale for the temporal variation of velocity. This is referred to as a high data density situation [29].

In many actual measurement situations, the data rate is not high enough (low data density) to actually characterize the flow. Here, sampling the output of the signal processor at uniform time increments will not work because the probability of getting an updated velocity (new data point) is higher at high velocity than at low velocity (velocity bias). The solution to the velocity bias problem is to weight the individual measurements with a factor inversely proportional to the probability of making the measurement.

\[ U = \frac{\sum u_j \tau_{Bj}}{\sum \tau_{Bj}} \]  

(29.71)

where \( u_j \) = Velocity of particle \( j \)
\( \tau_{Bj} \) = Transit time for particle \( j \)

Similar procedures can be used to obtain unbiased estimators for variance and other statistical properties of the flow [29]. Modern signal processors provide the residence time and the time between data points along with the velocity data. A comparison of some of the different approaches to do bias correction has been presented by Gould and Loseke [51]. Some of the other types of biases associated with LDV have been summarized by Edwards [52].

A variety of techniques to obtain spectral information of the flow velocity from the random data output of the signal processors have been tried. The goal of all these techniques has been to get accurate and unbiased spectral information to as high a frequency as possible. Direct spectral estimation of the digital output of the processors [53] exhibit the spectrum estimates at high frequency to be less reliable. The “slotting” technique [54, 55] of estimating the autocorrelation of the (random) velocity data followed
by Fourier transform continues to be attractive from a computational standpoint. To obtain reliable spectrum estimates at high frequencies, a variety of methods aimed at interpolation of measured velocity values have been attempted. These are generally referred to as data or signal reconstruction techniques. A review article [37] emphasizes the need to correct for velocity bias in the spectrum estimates. It also covers some of the recent reconstruction algorithms and points out the difficulties in coming up with a general-purpose approach.

**Extension to Particle Sizing**

In LDV, the frequency of the scattered light signal provides the velocity of the scatterer. Processing the scattered light to get information about the scatterer other than velocity has always been a topic of great interest in flow and particle diagnostics. One of the most promising developments is the extension of the LDV technique to measure the surface curvature and, hence, the diameter of a spherical scatterer [22]. This approach (limited to spherical particles) uses the phase information of the scattered light signal to extract the size information. To obtain a unique and, preferably, monotonic relation between phase of the signal and the size of the particle, the orientation and the geometry (aperture) of the scattered light collection system needs to be carefully chosen. In the following, unless otherwise mentioned, the particles are assumed to be spherical.

The light scattered by a particle, generally, contains contributions from the different scattering mechanisms — reflection, refraction, diffraction, and internal reflection(s). It can be shown that, by selecting the position of the scattered light collection set-up, contributions from one scattering mechanism can be made dominant over the others. The aim in phase Doppler measurements is to have the orientation of the receiver system such that the scattered light collected is from one dominant scattering mechanism.

The popularity of the technique is evidenced by its widespread use for measuring particle diameter and velocity in a large number of applications, especially in the field of liquid sprays [56]. The technique has also been used in diagnosing flow fields associated with combustion, cavitation, manufacturing processes, and other two-phase flows.

**Phase Doppler System: Principle**

The phase Doppler approach, outlined as an extension to an LDV system, was first proposed by Durst and Zare [57] to measure velocity and size of spherical particles. The first practical phase Doppler systems using a single receiver were proposed by Bachalo and Houser [22].

A schematic arrangement of a phase Doppler system is shown in Figure 29.30(a). This shows a receiver system arrangement that collects, separates, and focuses the scattered light onto multiple photodetectors. In general, the receiving system aperture is divided into three parts and the scattered light collected through these are focused into three separate photodetectors. For simplicity, in Figure 29.30(a), the output of two detectors are shown. The different spatial locations of the detectors (receiving apertures) results in the signals received by each detector having a slightly different phase. In general, the difference in phase between the signals from the detectors is used to obtain the particle diameter whereas the signal frequency provides the velocity of the particle.

**Fringe Model Explanation**

The fringe model provides an easy and straightforward approach to arrive at the expressions for Doppler frequency and phase shift created by a particle going through the measuring volume. As the particle moves through the fringes in the measuring volume, it scatters the fringe pattern (Figure 29.30(b)). The phase shift in the signals can be examined by looking at the scattered fringe pattern. If the particle acts like a spherical mirror (dominant reflection) or a spherical lens (dominant refraction), it projects fringes from the measuring volume into space all around as diverging bands of bright and dark light, known as scattered fringes. Scattered fringes as seen on a screen placed in front of the receivers are shown in Figure 29.30(b). The spacing between the scattered fringes at the plane of the receiver is \( s \). The receiver system shown in Figure 29.30(b) shows two apertures. The distance between (separation) the centroids
of the two receiving apertures is \( s_r \). Scattered fringes move across the receivers as the particle moves in the measuring volume, generating temporally fluctuating signals. The two photodetector output signals are shifted in phase by \( s_r / s_f \) times 360° [31]. Large particles create a scattered fringe pattern with a smaller fringe spacing (compared to that for small particles), i.e., particle diameter is inversely proportional to \( s_r \), while \( s_f \) is inversely proportional to phase difference. Thus, the fringe model shows the particle diameter to be directly proportional to the phase difference. It can also be seen that the sensitivity (degrees of phase difference per micrometer) of the phase Doppler system can be increased by increasing the separation \( (s_r) \) between the detectors.

The phase Doppler system shown above measures the phase difference between two detectors in the receiver system to obtain particle diameter. This brings in the limitation that the maximum value of phase that could be measured is \( 2\pi \). A three-detector arrangement in the receiver system is used to overcome this \( 2\pi \) ambiguity. Figure 29.31 shows the three-detector (aperture) arrangement. Scattered light collected through apertures 1, 2, and 3 are focused into detectors 1, 2, and 3. \( \Phi_{13} \) is the phase difference between the detectors 1 and 3 and provides the higher phase sensitivity because of their greater separation compared to detectors 1 and 2. As \( \Phi_{13} \) exceeds \( 2\pi \), the value of \( \Phi_{12} \) is below 360° and is used to keep track of \( \Phi_{13} \). It should be noted that the simplified approach in terms of geometrical scattering provides a linear relationship between the phase difference and diameter of the particle.

It has been pointed out that significant errors in measured size can occur due to trajectory-dependent scattering [58]. These errors could be minimized by choosing the appropriate optical configuration of the phase Doppler system [59]. An intensity-based validation technique has also been proposed to reduce the errors [60].
To explore the fundamental physical limits on applicability of the Phase Doppler technique, a rigorous model based on the electromagnetic theory of light has been developed. Computational results based on Mie scattering and comparison with and limitations of the geometric scattering approach have also been outlined by Naqwi and Durst [61]. These provided a systematic approach to develop innovative solutions to particle sizing problems. A new approach (PLANAR arrangement) to achieve high measurement resolution provided the ability to extend the measurement range to submicrometer particles. The Adaptive Phase Doppler Velocimeter (APV) system [59] that incorporates this layout uses a scattered light collection system that employs independent receivers. In the APV system, the separation between the detectors is selectable and is not dependent on the numerical aperture of the receiving system. Such a system was used for measuring submicrometer droplets in an electrospray [62]. By integrating a phase Doppler velocimeter system with a rainbow refractometer system, the velocity, size, and the refractive index of a droplet could be determined [63].

The velocity and diameter information is obtained by processing the photodetector output signals. The frequency of the photodetector output signal provides the velocity information. In general, the signal processing system for velocity measurements is expanded to measure the phase difference between two photodetector signals. The digital signal processing approaches described earlier have been complimented by the addition of accurate phase measurement techniques [64, 65].

Although the phase Doppler technique is limited to spherical particles, there has always been an interest in extending the technique to nonspherical particles. In the past, symmetry checks [66] and other similar techniques have been used to check on the sphericity of particles. An equivalent sphere approach has been used to describe these nonspherical particles. Sizing irregular particles is a more complex problem because the local radius of curvature concept is not meaningful in these cases. An innovative stochastic modeling approach has been used to study irregular particles using a phase Doppler system [67].

**Conclusion**

LDV has become the preferred technique for measuring flow velocity in a wide range of applications. The ability to measure noninvasively the velocity, without calibration, of any transparent flowing fluid has made it attractive for measuring almost any type of flow. Velocity measurement of moving surfaces by LDV is used to monitor and control industrial processes. Use of laser diodes, fiber optics, and advances in signal processing and data analysis are reducing both the cost and complexity of measuring systems. The extension of LDV to the phase Doppler technique provides an attractive, noncontact method for measuring size and velocity of spherical particles. Recent developments in the phase Doppler technique have generated a method to size submicrometer particles as well. These ideas have been extended to examine irregular particles also.
Acknowledgments

The input and comments from Dr. L. M. Fingerson and Dr. A. Naqwi of TSI Inc. have been extremely valuable in the preparation of this chapter section. The author is sincerely grateful to them for the help.

**Further Information**

30.1 Shear Viscosity

An important mechanical property of fluids is viscosity. Physical systems and applications as diverse as fluid flow in pipes, the flow of blood, lubrication of engine parts, the dynamics of raindrops, volcanic eruptions, planetary and stellar magnetic field generation, to name just a few, all involve fluid flow and are controlled to some degree by fluid viscosity. Viscosity is defined as the internal friction of a fluid. The microscopic nature of internal friction in a fluid is analogous to the macroscopic concept of mechanical friction in the system of an object moving on a stationary planar surface. Energy must be supplied (1) to overcome the inertial state of the interlocked object and plane caused by surface roughness, and (2) to initiate and sustain motion of the object over the plane. In a fluid, energy must be supplied (1) to create viscous flow units by breaking bonds between atoms and molecules, and (2) to cause the flow units to move relative to one another. The resistance of a fluid to the creation and motion of flow units is due to the viscosity of the fluid, which only manifests itself when motion in the fluid is set up. Since viscosity involves the transport of mass with a certain velocity, the viscous response is called a momentum transport process. The velocity of flow units within the fluid will vary, depending on location. Consider a liquid between two closely spaced parallel plates as shown in Figure 30.1. A force, \( F \), applied to the top plate causes the fluid adjacent to the upper plate to be dragged in the direction of \( F \). The applied force is communicated to neighboring layers of fluid below, each coupled to the driving layer above, but with diminishing magnitude. This results in the progressive decrease in velocity of each fluid layer, as shown by the decreasing velocity vector in Figure 30.1, away from the upper plate. In this system, the applied force is called a shear (when applied over an area it is called a shear stress), and the resulting deformation rate of the fluid, as illustrated by the velocity gradient \( dU_x/dz \), is called the shear strain rate, \( \dot{\gamma}_x \). The mathematical expression describing the viscous response of the system to the shear stress is simply:

\[
\tau_{xz} = \eta \frac{dU_x}{dz} = \eta \dot{\gamma}_x
\]

where \( \tau_{xz} \), the shear stress, is the force per unit area exerted on the upper plate in the \( x \)-direction (and hence is equal to the force per unit area exerted by the fluid on the upper plate in the \( x \)-direction under the assumption of a no-slip boundary layer at the fluid–upper plate interface); \( dU_x/dz \) is the gradient of the \( x \)-velocity in the \( z \)-direction in the fluid; and \( \eta \) is the coefficient of viscosity. In this case, because one is concerned with a shear force that produces the fluid motion, \( \eta \) is more specifically called the shear
**dynamic viscosity.** In fluid mechanics, diffusion of momentum is a more useful description of viscosity where the motion of a fluid is considered without reference to force. This type of viscosity is called the **kinematic viscosity**, \( \nu \), and is derived by dividing dynamic viscosity by \( \rho \), the mass density:

\[
\nu = \frac{\eta}{\rho}
\]  

The definition of viscosity by Equation 30.1 is valid only for **laminar** (i.e., layered or sheet-like) or streamline flow as depicted in Figure 30.1, and it refers to the molecular viscosity or **intrinsic viscosity**. The molecular viscosity is a property of the material that depends microscopically on bond strengths, and is characterized macroscopically as the fluid's resistance to flow. When the flow is turbulent, the diffusion of momentum is comprised of viscous contributions from the motion, sometimes called the **eddy viscosity**, in addition to the intrinsic viscosity. Viscosities of turbulent systems can be as high as 10^6 times greater than viscosities of laminar systems, depending on the Reynolds number.

**Molecular viscosity** is separated into **shear viscosity** and bulk or **volume viscosity**, \( \eta_s \), depending on the type of strain involved. Shear viscosity is a measure of resistance to isochoric flow in a shear field, whereas volume viscosity is a measure of resistance to volumetric flow in a three-dimensional stress field. For most liquids, including hydrogen bonded, weakly associated or unassociated, and polymeric liquids as well as liquid metals, \( \eta_s/\eta_v = 1 \), suggesting that shear and structural viscous mechanisms are closely related [1].

The shear viscosity of most liquids decreases with temperature and increases with pressure, which is opposite to the corresponding responses for gases. An increase in temperature usually causes expansion and a corresponding reduction in liquid bond strength, which in turn reduces the internal friction. Pressure causes a decrease in volume and a corresponding increase in bond strength, which in turn enhances the internal friction. For most situations, including engineering applications, temperature effects dominate the antagonistic effects of pressure. However, in the context of planetary interiors where the effects of pressure cannot be ignored, pressure controls the viscosity to the extent that, depending on composition, it can cause fundamental changes in the molecular structure of the fluid that can result in an anomalous viscosity decrease with increasing pressure [2].

**Newtonian and Non-Newtonian Fluids**

Equation 30.1 is known as Newton's law of viscosity and it formulates Sir Isaac Newton's definition of the viscous behavior of a class of fluids now called Newtonian fluids.
If the viscosity throughout the fluid is independent of strain rate, then the fluid is said to be a Newtonian fluid. The constant of proportionality is called the coefficient of viscosity, and a plot of stress vs. strain rate for Newtonian fluids yields a straight line with a slope of \( \eta \), as shown by the solid line flow curve in Figure 30.2. Examples of Newtonian fluids are pure, single-phase, unassociated gases, liquids, and solutions of low molecular weight such as water. There is, however, a large group of fluids for which the viscosity is dependent on the strain rate. Such fluids are said to be non-Newtonian fluids and their study is called rheology. In differentiating between Newtonian and non-Newtonian behavior, it is helpful to consider the time scale (as well as the normal stress differences and phase shift in dynamic testing) involved in the process of a liquid responding to a shear perturbation. The velocity gradient, \( dU_z/dz \), in the fluid is equal to the shear strain rate, \( \dot{\gamma} \), and therefore the time scale related to the applied shear perturbation about the equilibrium state is \( t_s \), where \( t_s = \frac{1}{\dot{\gamma}} \). A second time scale, \( t_r \), called the relaxation time, characterizes the rate at which the relaxation of the strain in the fluid can be accomplished and is related to the time it takes for a typical flow unit to move a distance equivalent to its mean diameter. For Newtonian water, \( t_r \approx 10^{-12} \) s and, because shear rates greater than \( 10^6 \text{ s}^{-1} \) are rare in practice, the time required for adjustment of the shear perturbation in water is much less than the shear perturbation period (i.e., \( t_s \ll t_r \)). However, for non-Newtonian macromolecular liquids like polymeric liquids, for colloidal and fiber suspensions, and for pastes and emulsions, the response times of large viscous flow units can easily make \( t_r > t_s \). An example of a non-Newtonian fluid is liquid elemental sulfur, in which long chains (polymers) of up to 100,000 sulfur atoms form flow units that are easily entangled, which bind the liquid in a "rigid-like" network. Another example of a well-known non-Newtonian fluid is tomato ketchup.

With reference to Figure 30.2, the more general form of Equation 30.1 also accounts for the nonlinear response. In terms of an initial shear stress required for flow to start, \( \tau_{xy}(0) \), an initial linear term in the Newtonian limit of a small range of strain rate, \( \dot{\gamma} \partial \tau_{xy}(0)/\partial \gamma \), and a nonlinear term \( O(\dot{\gamma}^2) \), the shear stress dependence on strain rate, \( \tau_{xy}(\dot{\gamma}) \) can be described as:

![FIGURE 30.2 Flow curves illustrating Newtonian and non-Newtonian fluid behavior.](image-url)
For a Newtonian fluid, the initial stress at zero shear rate is zero and the nonlinear function $O(\dot{\gamma}^2)$ is zero, so Equation 30.3 reduces to Equation 30.1, since $\partial \tau_{xy}(0)/\partial \dot{\gamma}$ then equals $\eta$. For a non-Newtonian fluid, $\tau_{xy}(0)$ may be zero but the nonlinear term $O(\dot{\gamma}^2)$ is nonzero. This characterizes fluids in which shear stress increases disproportionately with strain rate, as shown in the dashed-dotted flow curve in Figure 30.2, or decreases disproportionately with strain rate, as shown in the dashed flow curve in Figure 30.2. The former type of fluid behavior is known as shear thickening or dilatancy, and an example is a concentrated solution of sugar in water. The latter, much more common type of fluid behavior, is known as shear thinning or pseudo-plasticity; cream, blood, most polymers, and liquid cement are all examples. Both behaviors result from particle or molecular reorientations in the fluid that increase or decreases, respectively, the internal friction to shear. Non-Newtonian behavior can also arise in fluids whose viscosity changes with time of applied shear stress. The viscosity of corn starch and water increases with time duration of stress, and this is called rheopectic behavior. Conversely, liquids whose viscosity decreases with time, like nondrip paints, which behave like solids until the stress applied by the paint brush for a sufficiently long time causes them to flow freely, are called thixotropic fluids.

Fluid deformation that is not recoverable after removal of the stress is typical of the purely viscous response. The other extreme response to an external stress is purely elastic and is characterized by an equilibrium deformation that is fully recovered on removal of the stress. There are an infinite number of intermediate or combined viscous/elastic responses to external stress, which are grouped under the behavior known as viscoelasticity. Fluids that behave elastically in some stress range require a limiting or yield stress before they will flow as a viscous fluid. A simple, empirical, constitutive equation often used for this type of rheological behavior is of the form:

$$\tau_{x} = \tau_{y} + \dot{\gamma}^{n} \eta_{p}$$

(30.4)

where $\tau_{y}$ is the yield stress, $\eta_{p}$ is an apparent viscosity called the plastic viscosity, and the exponent $n$ allows for a range of non-Newtonian responses: $n = 1$ is pseudo-Newtonian behavior and is called a Bingham fluid; $n < 1$ is shear thinning behavior; and $n > 1$ is shear thickening behavior. Interested readers should consult [3–9] for further information on applied rheology.

**Dimensions and Units of Viscosity**

From Equation 30.1, the dimensions of dynamic viscosity are $M L^{-1} T^{-1}$ and the basic SI unit is the Pascal second (Pa·s), where 1 Pa·s = 1 N·s·m$^{-2}$. The c.g.s. unit of dyn·s·cm$^{-2}$ is the poise (P). The dimensions of kinematic viscosity, from Equation 30.2, are $L^2 T^{-1}$ and the SI unit is m$^2$·s$^{-1}$. For most practical situations, this is usually too large and so the c.g.s. unit of cm$^2$·s$^{-1}$, or the stoke (St), is preferred. Table 30.1 lists some common fluids and their shear dynamic viscosities at atmospheric pressure and 20°C.

Viscometer Types

The instruments for viscosity measurements are designed to determine “a fluid’s resistance to flow,” a fluid property defined above as viscosity. The fluid flow in a given instrument geometry defines the strain rates, and the corresponding stresses are the measure of resistance to flow. If strain rate or stress is set and controlled, then the other one will, everything else being the same, depend on the fluid viscosity. If the flow is simple (one dimensional, if possible) such that the strain rate and stress can be determined accurately from the measured quantities, the absolute dynamic viscosity can be determined; otherwise, the relative viscosity will be established. For example, the fluid flow can be set by dragging fluid with a sliding or rotating surface, falling body through the fluid, or by forcing the fluid (by external pressure or gravity) to flow through a fixed geometry, such as a capillary tube, annulus, a slit (between two parallel plates), or orifice. The corresponding resistance to flow is measured as the boundary force or torque, or pressure drop. The flow rate or efflux time represents the fluid flow for a set flow resistance, like pressure drop or gravity force. The viscometers are classified, depending on how the flow is initiated or maintained, as in Table 30.2.

The basic principle of all viscometers is to provide as simple flow kinematics as possible, preferably one-dimensional \((\text{isometric})\) flow, in order to determine the shear strain rate accurately, easily, and independent of fluid type. The resistance to such flow is measured, and thereby the shearing stress is

determined. The shear viscosity is then easily found as the ratio between the shearing stress and the corresponding shear strain rate. Practically, it is never possible to achieve desired one-dimensional flow nor ideal geometry, and a number of errors, listed in Table 30.3, can occur and need to be accounted for [4–8]. A list of manufacturers/distributors of commercial viscometers/rheometers is given in Table 30.4.

### Concentric Cylinders

The main advantage of the rotational as compared to many other viscometers is its ability to operate continuously at a given shear rate, so that other steady-state measurements can be conveniently performed. That way, time dependency, if any, can be detected and determined. Also, subsequent measurements can be made with the same instrument and sampled at different shear rates, temperature, etc. For these and other reasons, rotational viscometers are among the most widely used class of instruments for rheological measurements.

Concentric cylinder-type viscometers/rheometers are usually employed when absolute viscosity needs to be determined, which in turn, requires a knowledge of well-defined shear rate and shear stress data. Such instruments are available in different configurations and can be used for almost any fluid. There are models for low and high shear rates. More complete discussion on concentric cylinder viscometers/rheometers is given elsewhere [4–9]. In the Couette-type viscometer, the rotation of the outer cylinder, or cup, minimizes centrifugal forces, which cause Taylor vortices. The latter can be present in the Searle-type viscometer when the inner cylinder, or bob, rotates.

Note: All the above manufacturers can be found via the Internet (World Wide Web), along with the most recent contact information, product description and in some cases, pricing.
Usually, the torque on the stationary cylinder and rotational velocity of the other cylinder are measured for determination of the shear stress and shear rate, which is needed for viscosity calculation. Once the torque, $T$, is measured, it is simple to describe the fluid shear stress at any point with radius $r$ between the two cylinders, as shown in Figure 30.3.

In Equation 30.5, $L_e = (L + L_c)$, is the effective length of the cylinder at which the torque is measured. In addition to the cylinder’s length $L_e$, it takes into account the end-effect correction $L_c$ [4–8].

For a narrow gap between the cylinders ($b = R_2/R_1 > 1$), regardless of the fluid type, the velocity profile can be approximated as linear, and the shear rate within the gap will be uniform:

$$\tau_{\theta}(r) = \frac{T}{2\pi r^2 L_e}$$  \hspace{1cm} (30.5)

In Equation 30.5, $L_e = (L + L_c)$, is the effective length of the cylinder at which the torque is measured. In addition to the cylinder’s length $L_e$, it takes into account the end-effect correction $L_c$ [4–8].

For a narrow gap between the cylinders ($b = R_2/R_1 \equiv 1$), regardless of the fluid type, the velocity profile can be approximated as linear, and the shear rate within the gap will be uniform:

$$\gamma(r) \equiv \frac{\Omega \bar{R}}{(R_2 - R_1)}$$  \hspace{1cm} (30.6)

where $\Omega = (\omega_2 - \omega_1)$ is the relative rotational speed and $\bar{R} = (R_1 + R_2)/2$, is the mean radius of the inner (1) and outer (2) cylinders. Actually, the shear rate profile across the gap between the cylinders depends on the relative rotational speed, radii, and the unknown fluid properties, which seems an “open-ended” enigma. The solution of this complex problem is given elsewhere [4–8] in the form of an infinite series, and requires the slope of a logarithmic plot of $T$ as a function of $\Omega$ in the range of interest. Note that for a stationary inner cylinder ($\omega_1 = 0$), which is the usual case in practice, $\Omega$ becomes equal to $\omega_2$. 

© 1999 by CRC Press LLC
However, there is a simpler procedure [10] that has also been established by German standards [11]. For any fluid, including non-Newtonian fluids, there is a radius at which the shear rate is virtually independent of the fluid type for a given $\Omega$. This radius, being a function of geometry only, is called the representative radius, $R_R$, and is determined as the location corresponding to the so-called representative shear stress, \( \tau_R = (\tau_1 + \tau_2)/2 \), the average of the stresses at the outer and inner cylinder interfaces with the fluid, that is:

\[
R_R = R_1 \left\{ \frac{2\beta^2}{1 + \beta^2} \right\}^{1/2} = R_2 \left\{ \frac{2}{1 + \beta^2} \right\}^{1/2} \quad (30.7)
\]

Since the shear rate at the representative radius is virtually independent on the fluid type (whether Newtonian or non-Newtonian), the representative shear rate is simply calculated for Newtonian fluid ($n = 1$) and $r = R_R$, according to [10]:

\[
\dot{\gamma}_R = \dot{\gamma}_{r=R_R} = \omega_z \left\{ \frac{\beta^2 + 1}{\beta^2 - 1} \right\} \quad (30.8)
\]

The accuracy of the representative parameters depends on the geometry of the cylinders ($\beta$) and fluid type ($n$).

It is shown in [10] that, for an unrealistically wide range of fluid types ($0.35 < n < 3.5$) and cylinder geometries ($\beta = 1$ to 1.2), the maximum errors are less than 1%. Therefore, the error associated with the representative parameters concept is virtually negligible for practical measurements.

Finally, the (apparent) fluid viscosity is determined as the ratio between the shear stress and corresponding shear rate using Equations 30.5 to 30.8, as:

\[
\eta = \eta_R = \frac{\tau_R}{\dot{\gamma}_R} = \frac{T}{4\pi \beta^2 R_1^2 L_z} \frac{\beta^2 - 1}{\omega_z} \quad \frac{T}{4\pi \beta^2 R_1^2 L_z} \frac{\beta^2 - 1}{\omega_z} \quad (30.9)
\]

For a given cylinder geometry ($\beta$, $R_z$, and $L_z$), the viscosity can be determined from Equation 30.8 by measuring $T$ and $\omega_z$.

As already mentioned, in Couette-type viscometers, the Taylor vortices within the gap are virtually eliminated. However, vortices at the bottom can be present, and their influence becomes important when the Reynolds number reaches the value of unity [10, 11]. Furthermore, flow instability and turbulence will develop when the Reynolds number reaches values of $10^3$ to $10^4$. The Reynolds number, $Re$, for the flow between concentric cylinders is defined [11] as:

\[
Re = \left( \frac{\rho \omega_z R_1^2}{2\eta} \right) \left( \beta^2 - 1 \right) \quad (30.10)
\]

**Cone-and-Plate Viscometers**

The simple cone-and-plate viscometer geometry provides a uniform rate of shear and direct measurements of the first normal stress difference. It is the most popular instrument for measurement of non-Newtonian fluid properties. The working shear stress and shear strain rate equations can be easily derived in spherical coordinates, as indicated by the geometry in Figure 30.4, and are, respectively:
and

\[ \gamma = \frac{\Omega}{\theta_0} \quad (30.12) \]

where \( R \) and \( \theta_0 < 0.1 \text{ rad} (=6^\circ) \) are the cone radius and angle, respectively. The viscosity is then easily calculated as:

\[ \eta = \frac{\tau_0}{\gamma} = \frac{3R\theta_0}{2\pi R^3} \quad (30.13) \]

Inertia and secondary flow increase while shear heating decreases the measured torque \( (T_m) \). For more details, see [4, 5]. The torque correction is given as:

\[ \frac{T}{T_m} = 1 + 6 \cdot 10^{-4} \text{Re}^2 \quad (30.14) \]

where

\[ \text{Re} = \frac{\rho \left[ \theta_0 R^2 \right]^2}{\eta} \quad (30.15) \]
Parallel Disks

This geometry (Figure 30.5), which consists of a disk rotating in a cylindrical cavity, is similar to the cone-and-plate geometry, and many instruments permit the use of either one. However, the shear rate is no longer uniform, but depends on radial distance from the axis of rotation and on the gap $h$, that is:

$$\dot{\gamma}(r) = \frac{r\Omega}{h}$$  \hspace{1cm} \text{(30.16)}$$

For Newtonian fluids, after integration over the disk area, the torque can be expressed as a function of viscosity, so that the latter can be determined as:

$$\eta = \frac{2Th}{\pi\Omega R^4}$$  \hspace{1cm} \text{(30.17)}$$

Capillary Viscometers

The capillary viscometer is based on the fully developed laminar tube flow theory (Hagen–Poiseuille flow) and is shown in Figure 30.6. The capillary tube length is many times larger than its small diameter, so that entrance flow is neglected or accounted for in more accurate measurement or for shorter tubes. The expression for the shear stress at the wall is:

$$\tau_w = \left[\frac{\Delta P}{L}\right] \cdot \left[\frac{D}{4}\right]$$  \hspace{1cm} \text{(30.18)}$$

and
where, $C \equiv 1.1$, $P$, $z$, $V = 4Q/[\pi D^2]$, and $Q$ are correction factor, pressure, elevation, the mean flow velocity, and the fluid volume-flow rate, respectively. The subscripts 1 and 2 refer to the inlet and outlet, respectively.

The expression for the shear rate at the wall is:

$$
\Delta P = \left( P_1 - P_2 \right) + \left( z_1 - z_2 \right) - \frac{C\rho V^2}{2}
$$

where, $C \equiv 1.1$, $P$, $z$, $V = 4Q/[\pi D^2]$, and $Q$ are correction factor, pressure, elevation, the mean flow velocity, and the fluid volume-flow rate, respectively. The subscripts 1 and 2 refer to the inlet and outlet, respectively.

The expression for the shear rate at the wall is:

$$
\dot{\gamma} = \left[ \frac{3n+1}{4n} \right] \left[ \frac{8V}{D} \right]
$$

where $n = d[\log \tau_v]/d[\log (8V/D)]$ is the slope of the measured log($\tau_v$) – log ($8V/D$) curve. Then, the viscosity is simply calculated as:

$$
\eta = \frac{\tau_v}{\dot{\gamma}} = \left[ \frac{4n}{3n+1} \right] \left[ \frac{\Delta PD^2}{32LV} \right] = \left[ \frac{4n}{3n+1} \right] \left[ \frac{\Delta PD^2 \pi}{128QL} \right]
$$
Note that \( n = 1 \) for a Newtonian fluid, so the first term, \( \frac{4n}{3n+1} \), becomes unity and disappears from the above equations. The advantages of capillary over rotational viscometers are low cost, high accuracy (particularly with longer tubes), and the ability to achieve very high shear rates, even with high-viscosity samples. The main disadvantages are high residence time and variation of shear across the flow, which can change the structure of complex test fluids, as well as shear heating with high-viscosity samples.

**Glass Capillary Viscometers**

Glass capillary viscometers are very simple and inexpensive. Their geometry resembles a U-tube with at least two reservoir bulbs connected to a capillary tube passage with inner diameter \( D \). The fluid is drawn up into one bulb reservoir of known volume, \( V_0 \), between etched marks. The efflux time, \( \Delta t \), is measured for that volume to flow through the capillary under gravity.

From Equation 30.21 and taking into account that \( V_0 = \frac{D t}{4} \), \( D t \Delta P = \rho g (z_1 - z_2) \), the kinematic viscosity can be expressed as a function of the efflux time only, with the last term, \( K/\Delta t \), added to account for error correction, where \( K \) is a constant [7]:

\[
\nu = \frac{\eta}{\rho} = \left[ \frac{4n}{3n+1} \right] \frac{\pi g (z_1 - z_2) D^4}{128 L V_0} \left( \Delta t - K \Delta t \right) \tag{30.22}
\]

Note that for a given capillary viscometer and \( n \geq 1 \), the bracketed term is a constant. The last correction term is negligible for a large capillary tube ratio, \( L/D \), where kinematic viscosity becomes linearly proportional to measured efflux time. Various kinds of commercial glass capillary viscometers, like Cannon-Fenske type or similar, can be purchased from scientific and/or supply stores. They are the modified original Ostwald viscometer design in order to minimize certain undesirable effects, to increase the viscosity range, or to meet specific requirements of the tested fluids, like opacity, etc. Glass capillary viscometers are often used for low-viscosity fluids.

**Orifice/Cup, Short Capillary: Saybolt Viscometer**

The principle of these viscometers is similar to glass capillary viscometers, except that the flow through a short capillary (\( L/D < 10 \)) does not satisfy or even approximate the Hagen–Poiseuille, fully developed, pipe flow. The influences of entrance end-effect and changing hydrostatic heads are considerable. The efflux time reading, \( \Delta t \), represents relative viscosity for comparison purposes and is expressed as “viscometer seconds,” like the Saybolt seconds, or Engler seconds or degrees. Although the conversion formula, similar to glass capillary viscometers, is used, the constants \( k \) and \( K \) in Equation 30.23 are purely empirical and dependent on fluid types.

\[
\nu = \frac{\eta}{\rho} = k \Delta t - \frac{K}{\Delta t} \tag{30.23}
\]

where \( k = 0.00226, 0.0216, 0.073; \) and \( K = 1.95, 0.60, 0.0631; \) for Saybolt Universal (\( \Delta t < 100 \) s), Saybolt Furol (\( \Delta t > 40 \) s), and Engler viscometers, respectively [12, 13]. Due to their simplicity, reliability, and low cost, these viscometers are widely used for Newtonian fluids, like in oil and other industries, where the simple correlations between the relative properties and desired results are needed. However, these viscometers are not suitable for absolute viscosity measurement, nor for non-Newtonian fluids.

**Falling Body Methods**

**Falling Sphere**

The falling sphere viscometer is one of the earliest and least involved methods to determine the absolute shear viscosity of a Newtonian fluid. In this method, a sphere is allowed to fall freely a measured distance...
through a viscous liquid medium and its velocity is determined. The viscous drag of the falling sphere results in the creation of a restraining force, \( F \), described by Stokes’ law:

\[
F = 6\pi \eta r U_t \tag{30.24}
\]

where \( r \) is the radius of the sphere and \( U_t \) is the terminal velocity of the falling body. If a sphere of density \( \rho_s \) is falling through a fluid of density \( \rho_f \) in a container of infinite extent, then by balancing Equation 30.24 with the net force of gravity and buoyancy exerted on a solid sphere, the resulting equation of absolute viscosity is:

\[
\eta = 2gr^2 \frac{(\rho_s - \rho_f)}{9U_t} \tag{30.25}
\]

Equation 30.25 shows the relation between the viscosity of a fluid and the terminal velocity of a sphere falling within it. Having a finite container volume necessitates the modification of Equation 30.25 to correct for effects on the velocity of the sphere due to its interaction with container walls (\( W \)) and ends (\( E \)). Considering a cylindrical container of radius \( r \) and height \( H \), the corrected form of Equation 30.25 can be written as:

\[
\eta = 2gr^2 \frac{(\rho_s - \rho_f)W}{9U_tE} \tag{30.26}
\]

where

\[
W = 1 - 2.104 \left( \frac{r}{r} \right) + 2.09 \left( \frac{r}{r} \right)^3 - 0.95 \left( \frac{r}{r} \right)^5 \tag{30.27}
\]

\[
E = 1 + 3.3 \left( \frac{r}{H} \right) \tag{30.28}
\]

The wall correction was empirically derived \cite{15} and is valid for \( 0.16 \leq r_H \leq 0.32 \). Beyond this range, the effects of container walls significantly impair the terminal velocity of the sphere, thus giving rise to a false high viscosity value.

Figure 30.7 is a schematic diagram of the falling sphere method and demonstrates the attraction of this method — its simplicity of design. The simplest and most cost-effective approach in applying this method to transparent liquids would be to use a sufficiently large graduated cylinder filled with the liquid. With a distance marked on the cylinder near the axial and radial center (the region least influenced by the container walls and ends), a sphere (such as a ball bearing or a material that is nonreactive with the liquid) with a known density and sized to within the bounds of the container correction, free falls the length of the cylinder. As the sphere passes through the marked region of length \( d \) at its terminal velocity, a measure of the time taken to traverse this distance allows the velocity of the sphere to be calculated. Having measured all the parameters of Equation 30.26, the shear viscosity of the liquid can be determined.

This method is useful for liquids with viscosities between \( 10^{-3} \) Pa·s and \( 10^5 \) Pa·s. Due to the simplicity of design, the falling sphere method is particularly well suited to high pressure–high temperature viscosity studies.
Falling Cylinder

The falling cylinder method is similar in concept to the falling sphere method except that a flat-ended, solid circular cylinder freely falls vertically in the direction of its longitudinal axis through a liquid sample within a cylindrical container. A schematic diagram of the configuration is shown in Figure 30.8. Taking an infinitely long cylinder of density $\rho_2$ and radius $r_c$ falling through a Newtonian fluid of density $\rho_1$ with infinite extent, the resulting shear viscosity of the fluid is given as:

$$\eta = \frac{g r_c^2 (\rho_2 - \rho_1)}{2 U_i}$$

(30.29)

Just as with the falling sphere, a finite container volume necessitates modifying Equation 30.29 to account for the effects of container walls and ends. A correction for container wall effects can be analytically deduced by balancing the buoyancy and gravitational forces on the cylinder, of length $L$, with the shear force on the sides and the compressional force on the cylinder’s leading end and the tensile force on the cylinder’s trailing end. The resulting correction term, or geometrical factor, $G(k)$ (where $k = r_c/r$), depends on the cylinder radius and the container radius, $r$, and is given by:

$$G(k) = \frac{k^2 (1 - \ln k) - (1 + \ln k)}{(1 + k^2)}$$

(30.30)
Unlike the fluid flow around a falling sphere, the fluid motion around a falling flat-ended cylinder is very complex. The effects of container ends are minimized by creating a small gap between the cylinder and the container wall. If a long cylinder (here, a cylinder is considered long if $\psi \geq 10$, where $\psi = L/r$) with a radius nearly as large as the radius of the container is used, then the effects of the walls would dominate, thereby reducing the end effects to a second-order effect. A major drawback with this approach is, however, if the cylinder and container are not concentric, the resulting inhomogeneous wall shear force would cause the downward motion of the cylinder to become eccentric. The potential for misalignment motivated the recently obtained analytical solution to the fluid flow about the cylinder ends [16]. An analytical expression for the end correction factor (ECF) was then deduced [17] and is given as:

$$C_w = 1.003852 - 1.961019k + 0.9570952k^2.$$  

Equation 30.31 is valid for $\psi \leq 30$ and agrees with the empirically derived correction [16] to within 0.6%.

With wall and end effects taken into consideration, the working formula to determine the shear viscosity of a Newtonian fluid from a falling cylinder viscometer is:

$$\eta = \frac{g_r^2 (\rho_2 - \rho_1) G(k)}{2 U_1 \left( \frac{1}{ECF} \right)}.$$  

FIGURE 30.8  Schematic diagram of the falling cylinder viscometer. Using the same principle as the falling sphere, the velocity of the cylinder is obtained, which is needed to determine the shear viscosity of the fluid.
In the past, this method was primarily used as a method to determine relative viscosities between transparent fluids. It has only been since the introduction of the ECF [16, 17] that this method could be rigorously used as an absolute viscosity method. With a properly designed container and cylinder, this method is now able to provide accurate absolute viscosities from $10^{-3}$ Pa·s to $10^7$ Pa·s.

**Falling Methods in Opaque Liquids**

The falling body methods described above have been extensively applied to transparent liquids where optical (often visual) observation of the falling body is possible. For *opaque liquids*, however, falling body methods require the use of some sensing technique to determine, often *in situ*, the position of the falling body with respect to time. Techniques have varied but they all have in common the ability to detect the body as it moves past the sensor. A recent study at high pressure [18] demonstrated that the contrast in electric conductivity between a sphere and opaque liquid could be exploited to dynamically sense the moving sphere if suitably placed electrodes penetrated the container walls as shown in the schematic diagram in *Figure 30.9*. References to other similar *in situ* techniques are given in [18].
Rising Bubble/Droplet

For many industrial processes, the rising bubble viscometer has been used as a method of comparing the relative viscosities of transparent liquids (such as varnish, lacquer, and beer) for decades. Although its use was widespread, the actual behavior of the bubble in a viscous liquid was not well understood until long after the method was introduced [19]. The rising bubble method has been thought of as a derivative of the falling sphere method; however, there are primary differences between the two. The major physical differences are (1) the density of the bubble is less that of the surrounding liquid, and (2) the bubble itself has some unique viscosity. Each of these differences can, and do, lead to significant and extremely complex rheological problems that have yet to be fully explained. If a bubble of gas or droplet of liquid with a radius, \( r_b \), and density, \( \rho' \), is freely rising in some enclosing viscous liquid of density \( \rho \), then the shear viscosity of the enclosing liquid is determined by:

\[
\eta = \left( \frac{1}{\varepsilon} \right) \left[ \frac{2g r_b^3 (\rho - \rho')}{9 U_t} \right]
\]

(30.33)

where

\[
\varepsilon = \left( \frac{2\eta + 3\eta'}{3(\eta + \eta')} \right)
\]

(30.34)

where \( \eta' \) is the viscosity of the bubble. It must be noted that when the value of \( \eta' \) is large (solid spheres), \( \varepsilon = 1 \), which reduces Equation 30.33 to Equation 30.25. For small values of \( \eta' \) (gas bubbles), \( \varepsilon \) becomes 2/3, and the viscosity calculated by Equation 30.33 is 1.5 times greater than the viscosity calculated by Equation 30.25. It is apparent from Equation 30.33 and 30.25 that if the density of the bubble is less than the density of the enclosing liquid, and the terminal velocity of the sphere is negative, which indicates upward motion since the downward direction is positive.

During the rise, great care must be taken to avoid contamination of the bubble and its surface with impurities in the surrounding liquid. Impurities can diffuse through the surface of the bubble and combine with the fluid inside. Because the bubble has a low viscosity, the upward motion in a viscous medium induces a drag on the bubble that is responsible for generating a circulatory motion within it. This motion can efficiently distribute impurities throughout the whole of the bubble, thereby changing its viscosity and density. Impurities left on the surface of the bubble can form a "skin" that can significantly affect the rise of the bubble, as the skin layer has its own density and viscosity that are not included in Equation 30.33. These surface impurities also make a significant contribution to the inhomogeneous distribution of interfacial tension forces. A balance of these forces is crucial for the formation of a spherical bubble. The simplest method to minimize the above effects is to employ minute bubbles by introducing a specific volume of fluid (gas or liquid), with a syringe or other similar device, at the lower end of the cylindrical container. Very small bubbles behave like solid spheres, which makes interfacial tension forces and internal fluid motion negligible.

In all rising bubble viscometers, the bubble is assumed to be spherical. Experimental studies of the shapes of freely rising gas bubbles in a container of finite extent [20] have shown that (to 1% accuracy) a bubble will form and retain a spherical shape if the ratio of the radius of the bubble to the radius of the confining cylindrical container is less than 0.2. These studies have also demonstrated that the effect of the wall on the terminal velocity of a rising spherical bubble is to cause a large decrease (up to 39%) in the observed velocity compared to the velocity measured within an unbounded medium. This implies that the walls of the container influence the velocity of the rising bubble sooner than its geometry. In this method, end effects are known to be large. However, a rigorous, analytically or empirically derived
correction factor has not yet appeared. To circumvent this, the ratio of container length to sphere diameter must be in the range of 10 to 100. As in other Stokian methods, this allows the bubble's velocity to be measured at locations that experience negligible end effects.

Considering all of the above complications, the use of minute bubbles is the best approach to ensure a viscosity measurement that is least affected by the liquid to be investigated and the container geometry.

**Oscillating Method**

If a liquid is contained within a vessel suspended by some torsional system that is set in oscillation about its vertical axis, then the motion of the vessel will experience a gradual damping. In an ideal situation, the damping of the motion of the vessel arises purely as a result of the viscous coupling of the liquid to the vessel and the viscous coupling between layers in the liquid. In any practical situation, there are also frictional losses within the system that aid in the damping effect and must be accounted for in the final analysis. From observations of the amplitudes and time periods of the resulting oscillations, a viscosity of the liquid can be calculated. A schematic diagram of the basic set-up of the method is shown in Figure 30.10. Following initial oscillatory excitation, a light source (such as a low-intensity laser) can be used to measure the amplitudes and periods of the resulting oscillations by reflection off the mirror attached to the suspension rod to give an accurate measure of the logarithmic decrement of the oscillations ($\delta$) and the periods ($T$).

Various working formulae have been derived that associate the oscillatory motion of a vessel of radius $r$ to the absolute viscosity of the liquid. The most reliable formula is the following equation for a cylindrical vessel [21]:

$$\eta = \left[ \frac{I\delta}{\pi r HZ} \right]^2 \frac{1}{\pi \rho T}$$  \hspace{1cm} (30.35)
where

$$Z = \left( \frac{1 + r}{4H} \right) a_0 - \left( \frac{3}{2} + \frac{4r}{\pi H} \right) \frac{1}{\rho} + \left( \frac{3}{8} + \frac{9r}{4H} \right) a_2$$

(30.36)

$$p = \left( \frac{\pi \rho}{\eta T} \right)^{\gamma/2} r$$

(30.37)

$$a_0 = 1 - \left( \frac{\delta}{4\pi} \right) - \left( \frac{3\delta^2}{32\pi^2} \right)$$

(30.38)

$$a_2 = 1 + \left( \frac{\delta}{4\pi} \right) + \left( \frac{\delta^2}{32\pi^2} \right)$$

(30.39)

$I$ is the mass moment of inertia of the suspended system and $\rho$ is the density of the liquid.

A more practical expression of Equation 30.35 is obtained by introducing a number of simplifications. First, it is a reasonable assumption to consider $\delta$ to be small (on the order of $10^{-2}$ to $10^{-3}$). This reduces $a_0$ and $a_2$ to values of 1 and $-1$, respectively. Second, the effects of friction from the suspension system and the surrounding atmosphere can be experimentally determined and contained within a single variable, $\delta_0$. This must then be subtracted from the measured $\delta$. A common method of obtaining $\delta_0$ is to observe the logarithmic decrement of the system with an empty sample vessel and subtract that value from the measured value of $\delta$. With these modifications, Equation 30.35 becomes:

$$\frac{\delta - \delta_0}{\rho} = \left[ A \left( \frac{\eta}{\rho} \right)^{\gamma/2} - B \left( \frac{\eta}{\rho} \right) + C \left( \frac{\eta}{\rho} \right)^{\gamma/2} \right]$$

(30.40)

where

$$A = \left( \frac{\pi^{\gamma/2}}{I} \right) \left[ 1 + \left( \frac{r}{4H} \right) Hr^2T^{1/2} \right]$$

(30.41)

$$B = \left( \frac{\pi}{I} \right) \left[ \frac{3}{2} + \frac{4r}{\pi H} \right] Hr^2T$$

(30.42)

$$C = \left( \frac{\pi^{\gamma/2}}{2I} \right) \left[ \frac{3}{8} + \frac{9r}{4H} \right] HrT^{1/2}$$

(30.43)

It has been noted [22] that the analytical form of Equation 30.40 needs an empirically derived, instrument-constant correction factor ($\zeta$) in order to agree with experimentally measured values of $\eta$. The discrepancy between the analytical form and the measured value arises as a result of the above assumptions. However, these assumptions are required as there are great difficulties involved in solving
the differential equations of motion of this system. The correction factor is dependent on the materials, dimensions, and densities of each individual system, but generally lies between the values of 1.0 and 1.08. The correction factor is obtained by comparing viscosity values of calibration materials determined by an individual system (with Equation 30.35) and viscosity values obtained by another reliable method such as the capillary method.

With the above considerations taken into account, the final working Roscoe's formula for the absolute shear viscosity is:

$$
\frac{\delta - \delta_0}{\rho} = \zeta \left[ A \left( \frac{\eta}{\rho} \right)^{\frac{1}{2}} - B \left( \frac{\eta}{\rho} \right)^{\frac{3}{2}} + C \left( \frac{\eta}{\rho} \right)^{\frac{1}{2}} \right]
$$

(30.44)

The oscillating cup method has been used, and is best suited for use with low values of viscosity within the range of $10^{-5}$ Pa·s to $10^{-2}$ Pa·s. Its simple closed design and use at high temperatures has made this method very popular when dealing with liquid metals.

**Ultrasonic Methods**

Viscosity plays an important role in the absorption of energy of an acoustic wave traveling through a liquid. By using ultrasonic waves ($10^4$ Hz < $f$ < $10^8$ Hz), the elastic, viscoelastic, and viscous response of a liquid can be measured down to times as short as 10 ns. When the viscosity of the fluid is low, the resulting time scale for structural relaxation is shorter than the ultrasonic wave period and the fluid is probed in the relaxed state. High-viscosity fluids subjected to ultrasonic wave trains respond as a stiff fluid because structural equilibration due to the acoustic perturbation does not go to completion before the next wave cycle. Consequently, the fluid is said to be in an unrelaxed state that is characterized by dispersion (frequency-dependent wave velocity) and elastic moduli that reflect a much stiffer liquid. The frequency dependence of the viscosity relative to some reference viscosity ($\eta_0$), at low frequency, $\eta_0/\eta_0$, and of the absorption per wavelength, $\alpha\lambda$, where $\alpha$ is the absorption coefficient of the liquid and $\lambda$ is the wavelength of the compressional wave, for a liquid with a single relaxation time, $\tau$, is shown in Figure 30.11. The maximum absorption per wavelength occurs at the relaxation frequency when $\omega \tau = 1$

![Figure 30.11](image-url)  
**FIGURE 30.11** Effects of liquid relaxation (relaxation frequency corresponds to $\omega \tau = 1$ where $\omega = 2\pi f$) on relative viscosity (upper) and absorption per wavelength (lower) in the relaxed elastic ($\omega \tau < 1$) and unrelaxed viscoelastic ($\omega \tau > 1$) regimes.

© 1999 by CRC Press LLC
and is accompanied by a step in $\eta/\eta_0$, as well as in other properties such as velocity and compressibility. Depending on the application of the measured properties, it is important to determine if the liquid is in a relaxed or unrelaxed state.

A schematic diagram of a typical apparatus for measuring viscosity by the ultrasonic method is shown in Figure 30.12. Mechanical vibrations in a piezoelectric transducer travel down one of the buffer rods (BR-1 in Figure 30.12) and into the liquid sample and are received by a similar transducer mounted on the other buffer rod, BR-2. In the fixed buffer rod configuration, once steady-state conditions have been reached, the applied signal is turned off quickly. The decay rate of the received and amplified signal, displayed on an oscilloscope on an amplitude vs. time plot as shown in Figure 30.12(a), gives a measure of $\alpha$. The received amplitude decays as:

$$A = A_0 e^{-\left(b + \alpha \omega \right) t'}$$

where $A$ is the received decaying amplitude, $A_0$ is the input amplitude, $b$ is an apparatus constant that depends on other losses in the system such as due to the transducer, container, etc. that can be evaluated by measuring the attenuation in a standard liquid, $c$ is the compressional wave velocity of the liquid, and $t'$ is time. At low frequencies, the absorption coefficient is expressed in terms of volume and shear viscosity as:

$$\left(\eta_v + \frac{4\eta}{3}\right) = \frac{\alpha \rho c^3}{2\pi^2 f^2}$$

FIGURE 30.12 Schematic diagram of apparatus for liquid shear and volume viscosity determination by ultrasonic wave attenuation measurement showing the received signal amplitude through the exit buffer rod (BR-2) using (a) a fixed buffer rod configuration, and (b) an interferometric technique with movable buffer rod.
One of the earliest ultrasonic methods of measuring attenuation in liquids is based on *acoustic interferometry* [23]. Apart from the instrumentation needed to move and determine the position of one of the buffer rods accurately, the experimental apparatus is essentially the same as for the fixed buffer rod configuration [24]. The measurement, however, depends on the continuous acoustic wave interference of transmitted and reflected waves within the sample melt as one of the buffer rods is moved away from the other rod. The attenuation is characterized by the decay of the maxima amplitude as a function of melt thickness as shown on the interferogram in Figure 30.12(b). Determining $\alpha$ from the observed amplitude decrement involves numerical solution to a system of equations characterizing complex wave propagation [25]. The ideal conditions represented in the theory do not account for such things as wave front curvature, buffer rod end nonparallelism, surface roughness, and misalignment. These problems can be addressed in the amplitude fitting stage but they can be difficult to overcome. The interested reader is referred to [25] for further details.

Ultrasonic methods have not been and are not likely to become the mainstay of fluid viscosity determination simply because they are more technically complicated than conventional viscometry techniques. And although ultrasonic viscometry supplies additional related elastic property data, its niche in viscometry is its capability of providing volume viscosity data. Since there is no other viscometer to measure $\eta_v$, ultrasonic absorption measurements play a unique role in the study of volume viscosity.

**Further Information**

The effect of surface tension is observed in many everyday situations. For example, a slowly leaking faucet drips because the force of surface tension allows the water to cling to it until a sufficient mass of water is accumulated to break free. Surface tension can cause a steel needle to “float” on the surface of water although its density is much higher than that of water. The surface of a liquid can be thought of as having a skin that is under tension. A liquid droplet is somewhat analogous to a balloon filled with air. The elastic skin of the balloon contains the air inside at a slightly higher pressure than the surrounding air. The surface of a liquid droplet likewise contains the liquid in the droplet at a pressure that is slightly higher than ambient. A clean liquid surface, however, is not elastic like a rubber skin. The tension in a piece of rubber increases as it is stretched and will eventually rupture. A clean liquid surface can be expanded indefinitely without changing the surface tension.

The mechanical model of the liquid surface is that of a skin under tension. Any given patch of the surface thus experiences an outward force tangential to the surface everywhere on the perimeter. The force per unit length of the perimeter acting perpendicular to the perimeter is defined as the surface tension, $\gamma$. Molecules in the interfacial region have a higher potential energy than molecules in the bulk phases because of an imbalance of intermolecular attractive forces. This results in an excess free energy per unit area associated with the surface that is numerically equivalent to the surface tension, as shown below. Consider a flat rectangular patch of fluid interface of width $W$ and length $L$. In order to expand the length to $L + \Delta L$, an amount of work $\gamma W \Delta L$ must be done at the boundary. The product $W \Delta L$ is just the change in area $\Delta A$ of the surface. The work done to increase the area is thus $\Delta A \gamma$, which corresponds to the increase in surface free energy. Thus, the surface tension $\gamma$ is seen to be equivalent to the surface free energy per unit area.

Room-temperature organic liquids typically have surface tensions in the range of 20 mN m$^{-1}$ to 40 mN m$^{-1}$, while pure water has a value of 72 mN m$^{-1}$ at 25°C. The interface between two immiscible liquids, such as oil and water, also has a tension associated with it, which is generally referred to as the interfacial tension.

The surface energy concept is useful for understanding the shapes adopted by liquid surfaces. An isolated system in equilibrium is in a state of minimum free energy. Because the surface free energy contributes to the total free energy of a multiphase system, the surface free energy is minimized at
equilibrium subject to certain constraints. Also, because the surface free energy is directly proportional to the surface area, surface area is also minimized. In the absence of gravity, a free-floating liquid droplet assumes a spherical shape because, for a given volume of liquid, the sphere has the least surface area. However, a droplet suspended from a needle tip on Earth does not form a perfect sphere because the minimum free energy configuration involves a trade-off between a reduction of the surface energy and a reduction of the gravitational potential. The droplet elongates to reduce its gravitational potential energy.

The surface energy concept is also useful for understanding the behavior of so-called surface active agents or surfactants. A two-component liquid mixture in thermodynamic equilibrium exhibits preferential adsorption of one component at the surface if the adsorption causes a decrease in the surface energy. The term surfactant is reserved for molecular species that strongly absorb at the surface even when their concentration in the bulk liquid is very low. Surfactants are common in natural waters and are very important in many biological and industrial processes.

The interface between a solid and a fluid also has a surface free energy associated with it. Figure 31.1(a) shows a liquid droplet at rest on a solid surface surrounded by air. This system contains three different types of interfaces: solid–gas, solid–liquid, and liquid–gas, each with a characteristic surface free energy per unit area. The state of minimum free energy for the system then involves trade-offs in the surface area for the various interfaces. The region of contact between the gas, liquid, and solid is termed the contact line. The liquid–gas surface meets the solid surface with an angle \( \theta \) measured through the liquid, which is known as the contact angle. The contact angle attains a value that minimizes the free energy of the system and is thus a characteristic of a particular solid–liquid–gas system. The system shown in Figure 31.1(a) has a smaller contact angle than that shown in Figure 31.1(b). The smaller the contact angle, the better the liquid is said to wet the solid surface. For \( \theta = 0 \), the liquid is said to be perfectly wetting.

Measurement of surface tension is important in many fields of science and engineering, as well as in medicine. A number of standard methods exist for its measurement. In many systems of interest, the surface tension changes with time, perhaps, for example, because of adsorption of surfactants. Several standard methods can be used to measure dynamic surface tension if it changes slowly with time. Special techniques have been developed to measure dynamic surface tensions for systems that evolve very rapidly.

### 31.1 Mechanics of Fluid Surfaces

Some methods of measuring surface tension depend on the mechanics at the line of contact between a solid, liquid, and gas. When the system is in static mechanical equilibrium, the contact line is motionless, meaning that the net force on the line is zero. Forces acting on the contact line arise from the surface tensions of the converging solid–gas, solid–liquid, and liquid–gas interfaces, denoted by \( \gamma_{SG} \), \( \gamma_{SL} \), and \( \gamma_{LG} \), respectively (Figure 31.2). The condition of zero net force along the direction tangent to the solid surface gives the following relationship between the surface tensions and contact angle \( \theta \):

\[
\gamma_{SL} \cos \theta = \gamma_{SG} + \gamma_{LG}
\]
This is known as Young's equation. The contact angle is thus seen to be dependent on the surface tensions between the various phases present in the system, and is therefore an intrinsic property of the system.

As discussed in the introduction, the surface tension of a droplet causes an increase in pressure in the droplet. This can be understood by considering the forces acting on a curved section of surface as illustrated in Figure 31.3(a). Because of the curvature, the surface tension forces pull the surface toward the concave side of the surface. For mechanical equilibrium, the pressure must then be greater on the concave side of the surface. Figure 31.3(b) shows a saddle-shaped section of surface in which surface tension forces oppose each other, thus reducing or eliminating the required pressure difference across the surface. The mean curvature of a two-dimensional surface is specified in terms of the two principal radii of curvature, $R_1$ and $R_2$, which are measured in perpendicular directions. A detailed mechanical analysis of curved tensile surfaces shows that the pressure change across the surface is directly proportional to the surface tension and to the mean curvature of the surface:

$$P_A - P_B = \gamma \left( \frac{1}{R_1} + \frac{1}{R_2} \right)$$ (31.2)
where $\gamma$ is the surface tension, and the quantity in brackets is twice the mean curvature. The sign of the radius of curvature is positive if its center of curvature lies in phase A and negative if it lies in phase B. Equation 31.2 is known as the Young–Laplace equation, and the pressure change across the interface is termed the Laplace pressure. Measurement of the Laplace pressure for a surface of known curvature then allows a determination of the surface tension.

Several methods of surface tension measurement are based on the measurement of the static shape of an axisymmetric drop or bubble or on the point of mechanical instability of such drops or bubbles. In a gravitational field a drop or bubble that is attached to a solid support assumes a nonspherical shape. Figure 31.4(a) shows the shape of a hanging droplet, also known as a pendant drop, and Figure 31.4(b) shows a so-called sessile drop. Axisymmetric air bubbles in water attain the same shapes as water drops in air, except that they are inverted. A bubble supported from below is thus called a hanging or pendant bubble, and a bubble supported from above is called a captive or sessile bubble. The reason for the deviation of the shape from that of a sphere can be understood from Equation 31.2. The hydrostatic pressure changes with depth more rapidly in a liquid than in a gas. The pressure difference across the surface of a pendant drop in air therefore increases from top to bottom, requiring an increase in the mean curvature of the surface according to Equation 31.2. The drop in Figure 31.4(a) has a neck at the top, which means that the two principal radii of curvature have opposite signs and cancel to some extent. At the bottom of the drop, the radii of curvature have the same sign, thus making the mean curvature larger. The Young–Laplace equation can be written as coupled first-order differential equations in terms of the coordinates of the interface for an axisymmetric surface in a gravitational field as:

$$\frac{dx}{ds} = \cos \phi$$

$$\frac{dz}{ds} = \sin \phi$$

Figure 31.4

(a) A pendant drop showing the characteristic dimensions, $d_e$, and $d_s$, and the coordinates used in the Young–Laplace equation. (b) A sessile drop showing the characteristic dimensions $R$ and $h$. 
where \( x \) and \( z \) are the horizontal and vertical coordinates, respectively, with the origin at the drop apex; \( s \) is the arc-length along the drop surface measured from the drop apex; and \( \phi \) is the angle between the surface tangent and the horizontal (Figure 31.4(a)). The parameter \( b \) is the radius of curvature at the apex of the drop or bubble, \( \Delta \rho \) is the density difference between the two fluid phases, and \( g \) is the acceleration of gravity. Numerical integration of Equation 31.3 allows one to compute the shape of an axisymmetric fluid interface. Comparison of computed shapes with experimentally measured shapes of drops or bubbles is a useful method of measuring surface tension. If all lengths in Equation 31.3 are made dimensionless by dividing them by \( b \), the resulting equation contains only one parameter, \( \beta = \frac{\Delta \rho g b^2}{\gamma} \), which is called the Bond number (or shape factor). The shape of an axisymmetric drop, bubble, or meniscus depends only on this one dimensionless parameter. The Bond number can also be written as \( \beta = \frac{2 \gamma}{\Delta \rho g} \) where \( a = \frac{\sqrt{2 \gamma}}{\Delta \rho g} \) is known as the capillary constant and has units of length.

Several dynamic methods of measuring surface tension are based on capillary waves. Capillary waves result from oscillations of the liquid surface for which surface tension is the restoring force. The frequency of the surface oscillation is thus dependent on the surface tension and wavelength. Very low amplitude capillary waves with a broad range of frequencies are always present on liquid surfaces owing to thermal fluctuations. Larger amplitude capillary waves can be excited by purposely perturbing the surface.

### 31.2 Standard Methods and Instrumentation

A number of commonly used methods of measuring surface tension exist. The choice of a method depends on the system to be studied, the degree of accuracy required, and possibly on the ability to automate the measurements. In the discussion that follows, these methods are grouped according to the kind of instruments used in the measurements. Because the information presented for each method is necessarily brief, readers who are interested in constructing their own apparatus should consult the more detailed treatises in [1–4]. A list of commercially available instruments is given in Table 31.1, together with manufacturer names and approximate prices. Vendors can be contacted at the addresses given in Table 31.2.

Capillary Rise Method

If a glass capillary tube is brought into contact with a liquid surface, and if the liquid wets the glass with a contact angle of less than 90°, then the liquid is drawn up into the tube as shown in Figure 31.5(a). The surface tension is directly proportional to the height of rise, \( h \), of the liquid in the tube relative to the flat liquid surface in the larger container. By applying Equation 31.2 to the meniscus in the capillary tube, the following relationship is obtained:

\[
\Delta \rho g h = \frac{2\gamma}{b}
\]

(31.4)

where \( b \) is the radius of curvature at the center of the meniscus and \( \Delta \rho \) is the density difference between liquid and gas. For small capillary tubes, \( b \) is well approximated by the radius of the tube itself, assuming that the contact angle of the liquid on the tube is zero. For larger tubes or for increased accuracy, the
value of \( b \) must be corrected for gravitational deformation of the meniscus (p. 12 of [1]). Obtaining accurate results with the capillary rise method requires using a thoroughly clean glass capillary tube with a very uniform diameter of less than 1 mm. The container for the liquid should be at least 8 cm in diameter and the liquid must wet the capillary tube with a contact angle of zero. This method is primarily useful for pure liquids and is capable of high accuracy at relatively low cost.

**Wilhelmy Plate and du Noüy Ring Methods**

Measurement of the pull of a liquid surface directly on a solid object is the basis for two of the standard methods discussed here. In the Wilhelmy plate method, the solid object is a flat, thin plate that the test liquid should wet with a zero contact angle. The plate is suspended vertically from a delicate balance that is zeroed with the plate suspended in air. The test liquid is brought into contact with the bottom of the plate, causing the plate to be pulled down into the liquid by the surface tension force. The force applied to the plate from above is then increased to bring the bottom edge of the plate level with the flat surface of the liquid (Figure 31.5(b)). This avoids the necessity to make buoyancy corrections to the measurement. The surface tension is computed from the force measurement, \( f \), using:
where \( l \) is the length of the plate and \( t \) is its thickness. The contact angle \( \theta \) is often assumed to be zero for common liquids on clean glass or platinum plates, but one should be aware of the error caused by a non-zero contact angle. No other correction factors are necessary for this method and the fluid density does not need to be known.

The du Noüy ring method is known as a maximum pull method, of which there are several variations. The technique is to contact the liquid surface with a ring and then measure the force continuously as the surface is lowered until a maximum force, \( f_{\text{max}} \), is recorded. The maximum force typically occurs just before the ring detaches from the surface. The surface tension is obtained from the formula:

\[
\gamma = \frac{f \cos \theta}{2(l + t)} \tag{31.5}
\]

where \( R \) and \( r \) are the radii of the ring and wire, respectively, as indicated in Figure 31.5(c), \( V \) is the volume of liquid raised by the ring, and \( F \) is a correction factor (\( F \) is tabulated in Table 5, p. 132 of [4]). The du Noüy ring method requires knowledge of the liquid density, \( \rho_L \), in order to determine \( V \) from \( V = f_{\text{max}}/\rho_L \). This method requires the liquid to wet the ring with zero contact angle and is not suitable for solutions that attain surface equilibrium slowly.

A single instrument is normally capable of performing either Wilhelmy plate or du Noüy ring measurements. Some commercially available instruments can perform the complete measurement procedure automatically. Computer interfacing with a Wilhelmy plate instrument allows automatic data logging which can be used to follow changes in surface tension with time in surfactant solutions.

**Maximum Bubble Pressure Method**

The **maximum bubble pressure method** (MBPM) involves direct measurement of the pressure in a bubble to determine the surface tension. A tube is lowered to a depth \( t \) in the test liquid and gas is injected to form a bubble of height \( Z_b \) at the tip of the tube as shown in Figure 31.5(d). The increase in bubble pressure, \( P_b \), over ambient pressure, \( P_a \), arising from the interface is given by the sum of a hydrostatic pressure and Laplace pressure:

\[
\delta p = P_b - P_a - \Delta \rho g t = \Delta \rho g Z_b + \frac{2\gamma}{b} \tag{31.7}
\]

As a new bubble begins to form, \( Z_b \) increases while \( b \), the radius of curvature at the bubble apex, decreases, resulting in an increase in pressure in the bubble. Ultimately, \( b \) increases as the bubble grows larger, thus reducing the pressure. The pressure in the bubble thus reaches a maximum when \( \delta p \) reaches a maximum, which in turn can be theoretically related to the surface tension. For \( \delta p = \delta p_{\text{max}} \), Equation 31.7 can be rewritten in dimensionless form as follows:

\[
\frac{r}{X} = \frac{r}{b} + \frac{r}{a} \frac{Z_b}{b} \left( \frac{\beta}{2} \right)^{1/2} \tag{31.8}
\]

where \( r \) is the tube radius, \( X \) is a length defined as \( X = \frac{2\gamma}{\delta p_{\text{max}}} \), \( a \) is the capillary constant, and \( \beta \) is the Bond number. The dimensionless quantity \( r/X \) depends only on \( r/a \), the relationship being determined by Equation 31.8 combined with numerical solutions of Equation 31.3. Tabulations of this relationship...
are used to calculate the surface tension by an iterative procedure (p. 18 of [1]). The standard MBPM requires a knowledge of the fluid densities, tube radius, and depth of immersion of the tube.

A differential MBPM uses two tubes of different diameters immersed to the same depth. The difference in the maximum bubble pressure for the two tubes, \( \Delta P \), is measured, eliminating the need to know the immersion depth and making the method less sensitive to errors in the knowledge of the liquid density. For the differential MBPM, surface tension is computed from (see [5]):

\[
\gamma = A \Delta P \left[ 1 + \left( \frac{0.69 r_L \rho}{\Delta P} \right) \right]
\]  

(31.9)

where \( r_L \) is the radius of the larger tube, \( \rho_L \) is the liquid density, and \( A \) is an apparatus-dependent constant that is determined by calibration with several standard liquids [6]. Automated MBPM units are commercially available (see Table 31.1). Sensa Dyne manufactures differential MBPM units that allow for online process measurements under conditions of varying temperature and pressure.

Pendant Drop and Sessile Drop Methods

The shape of an axisymmetric pendant or sessile drop (Figure 31.4) depends on only a single parameter, the Bond number, as discussed above. The Bond number is a measure of the relative importance of gravity to surface tension in determining the shape of the drop. For Bond numbers near zero, surface tension dominates and the drop is nearly spherical. For larger Bond numbers, the drop becomes significantly deformed by gravity. In principle, the method involves obtaining an image of the drop and comparing its shape and size to theoretical profiles obtained by integrating Equation 31.3 for various values of \( \beta \) and \( b \). Once \( \beta \) and \( b \) have been determined from shape and size comparison, the surface tension is calculated from:

\[
\gamma = \frac{\Delta \rho_gb^2}{\beta}
\]  

(31.10)

In practice, the drop shape and size has traditionally been determined by the manual measurement of several characteristic dimensions (see Figure 31.4) of the drop from a photographic print. For pendant drops, the ratio \( d_s/d_e \) is correlated to a shape factor \( H \) from which surface tension is calculated (p. 27 of [3], [7]) according to:

\[
\gamma = \frac{\Delta \rho_gd_s^3}{H}
\]  

(31.11)

For sessile drops, various analytical formulae are available for computation of surface tension directly from the characteristic dimensions (p. 36 of [3]). Drop shape methods based on characteristic dimensions require very accurate measurement of the dimensions for good results. For more accurate results, methods that fit the entire shape of the edge of the drop to the Laplace equation are recommended.

In recent years, the entire procedure has been automated using digital imaging and computer image analysis [8, 9]. Typically, several hundred coordinates on the edge of the drop are located with subpixel resolution by computer analysis of the digital image. The size, shape, and horizontal and vertical offsets of the theoretical profile given by Equation 31.3 are varied by varying four parameters: \( b, \beta, \) and the pixel coordinates of the drop apex, \( x_0 \) and \( z_0 \). A best fit of the theoretical profile to the measured edge coordinates is obtained by minimizing an objective function. A digital image of a pendant drop can be analyzed for surface tension on a desktop computer in 1 or 2 s [10]. The speed of algorithms for pendant drop analysis on modern desktop computers has allowed this method to be used to track changes in surface tension for surfactant-covered surfaces by analyzing a sequence of images. The algorithms can simultaneously
track the surface area and volume of the drop or bubble. Both soluble and insoluble surfactants have been studied using the pendant drop, sessile drop, pendant bubble, and captive bubble configurations [11–13]. Table 31.1 lists several manufacturers that can provide software for automated analysis of surface tension from drops or bubbles in pendant or sessile configurations. The increased accuracy and simplicity of the automated pendant drop procedure makes it a very flexible method that has been applied to measure ultralow interfacial tensions, pressure, temperature and time dependence of interfacial tension, relaxation of adsorption layers, measurement of line tensions, and film-balance measurements [14].

**Drop Weight or Volume Method**

A pendant drop will become unstable and detach from its support if it grows too large. The weight of the detached portion is related to the surface tension of the fluid by:

\[
\gamma = \left( \frac{mg}{r} \right) \left( F \left( \frac{r}{V^{1/3}} \right) \right)
\]

(31.12)

where \(mg\) is the weight of the detached drop, \(r\) is the radius of the tip from which the drop hangs, and \(V\) is the volume of the detached drop. An empirical correction factor, \(F\), is tabulated as a function of \(r/V^{1/3}\) (p. 50 of [3]). For Equation 31.12 to apply, drops must be formed slowly. Measurements typically involve weighing the accumulated liquid from a large number of drops to determine the average weight per drop. The density of the fluid must be known in order to determine the drop volume and then obtain the factor \(F\). Another method involves measuring the volumetric flow rate of liquid to the tip while counting the drops. The density of the fluid must be known in order to determine the drop weight. The latter method allows for automation of measurements [15].

**Spinning Drop Method**

The spinning drop method is a shape-measurement method similar to the pendant and sessile drop methods. However, the deformation of the drop in this case is caused by radial pressure gradients in a rapidly spinning tube. This method is normally used for measuring interfacial tensions between immiscible liquids. A horizontal glass tube with sealed ends is filled with the more dense liquid through a filling port. The tube is then spun about its axis while a drop of the lower density liquid is injected into the tube. The pressure in the outer liquid increases from the center of the tube toward the walls as a result of the spinning motion. The pressure gradient forces the drop to move to the center of the tube and causes it to elongate, while surface tension opposes elongation. Measurement of the maximum drop diameter, \(2r_{\text{max}}\), and length, \(2h_{\text{max}}\), together with the angular velocity of rotation, \(\Omega\), allows for calculation of the surface tension according to:

\[
\gamma = \frac{1}{2} \left( \frac{r_{\text{max}}}{r_{\text{max}}^{*}} \right)^{3} \Delta \rho \Omega^{2}
\]

(31.13)

where \(r_{\text{max}}^{*}\) is correlated to the aspect ratio \(r_{\text{max}}/h_{\text{max}}\) [16]. The spinning drop method is particularly suited for measuring ultralow interfacial tensions (10–2 mN m–1 to 10–4 mN m–1).

**31.3 Specialized Methods**

**Dynamic Surface Tension**

In an aqueous solution of soluble surfactant, the surface tension decreases following creation of new surface area because of adsorption of surfactant molecules. Surfactant adsorption kinetics can be studied
by measuring the change in surface tension with time. For a dilute solution, the rate of change of surface tension is often slow enough that automated versions of static methods such as the Wilhelmy plate or pendant drop [17] methods can be used to follow the changes in surface tension. In concentrated solutions in which large changes in surface tension can occur within a fraction of a second following surface creation, a dynamic method must be used. A liquid jet emerging from an elliptical orifice has stationary waves on its surface, the wavelengths of which are related to the surface tension. The oscillating jet method has been used to measure surface tension for surface ages as low as 0.6 ms [18]. A dynamic version of the maximum bubble pressure method has been used to measure dynamic surface tension at surface ages down to 0.1 ms [19].

**Surface Viscoelasticity**

A liquid surface covered by a monolayer of surfactant exhibits viscoelastic behavior. In addition to surface tension, the surface rheology is characterized in terms of dilatational and shear elasticities as well as dilatational and shear viscosities. The dilatational properties in particular are important in a variety of situations from foam stability to the functioning of the human lung. The surface dilatational modulus is proportional to the change in surface tension for a given change in surface area. This modulus depends on the rate of change of surface area for both soluble and insoluble surfactant monolayers, which indicates that relaxation processes are active. These relaxation processes give rise to the surface dilatational viscosity. For the case of soluble surfactants, one of the relaxation processes is the adsorption or desorption of molecules at the surface. The equilibrium dilatational elasticity of an insoluble monolayer can be measured by slowly expanding or compressing the monolayer in a Langmuir trough while monitoring the surface tension with a Wilhelmy plate apparatus [20]. Studies of surface rheology at high rates of surface expansion or compression are of interest for both soluble and insoluble surfactants.

Surface tension relaxation following sudden expansion or compression of the surface for a soluble surfactant has been studied by the automated pendant drop method [21]. A method known as oscillating bubble tensiometry has been applied to measure the kinetics of adsorption and desorption for soluble surfactants [22, 23]. Other methods for studying dynamic dilatational viscoelastic properties are reviewed in [24], including transverse and longitudinal capillary wave methods, a modified maximum bubble pressure method, and an oscillating bubble method.

**Measurements at Extremes of Temperature and Pressure**

Several of the standard methods described in this chapter can be adapted to make surface or interfacial tension measurements at extreme temperatures and/or pressures. The most common methods used to measure the surface tension of high-temperature molten metals, alloys, and semiconductors are the maximum bubble pressure method [25] and the pendant or sessile drop method [26–28]. Measurement of the interfacial tension between oil and a second immiscible phase at high pressure and elevated temperature is of interest for understanding aspects of enhanced oil recovery. The pendant drop method has been applied under pressures of 82 MPa at 449 K [29], while a capillary wave method has been applied at 136 MPa and 473 K [30]. A pendant drop apparatus capable of measurements to 10,000 psi (69 MPa) and 350°F (450 K) is commercially available from Temco Inc. (Table 31.2).

**Interfacial Tension**

Measurement of the interfacial tension between two immiscible liquids can present special difficulties. Measurement by the capillary rise, du Noüy ring, or Wilhelmy plate method is problematic in that the contact angle is often nonzero. The pendant drop [7] and drop weight [31] methods can both be applied, provided the densities of the two liquids are sufficiently different. The pendant drop method, in particular, is widely used for interfacial tension measurement. Interfacial tension can be measured by a modified maximum bubble pressure method in which one measures the maximum pressure in a liquid drop injected into a second immiscible liquid [32]. The modified maximum bubble pressure method [32] and
a liquid bridge method [33] have been used to measure interfacial tension between two liquids of equal
density. Ultralow values of interfacial tension can be measured by the spinning drop [34], pendant drop
[35], and capillary wave methods [34].

**Defining Terms**

**Surface tension:** A force per unit length that acts tangential to a liquid surface and perpendicular to
any line that lies within the surface.

**Surface energy:** The excess free energy per unit area associated with a surface between two phases. For
a liquid–fluid surface, the surface energy is numerically equivalent to the surface tension.

32.1 Bimaterials Thermometers

Robert J. Stephenson, Armelle M. Moulin, and Mark E. Welland

The first known use of differential thermal expansion of metals in a mechanical device was that of the English clockmaker John Harrison in 1735. Harrison used two dissimilar metals in a clock escapement to account for the changes in temperature on board a ship. This first marine chronometer used a gridiron of two metals that altered the flywheel period of the clock through a simple displacement. This mechanical actuation, resulting from the different thermal expansivities of two metals in contact, is the basis for all bimetallic actuators used today.

The bimetallic effect is now used in numerous applications ranging from domestic appliances to compensation in satellites. The effects can be used in two ways: either as an actuator or as a temperature measuring system. A bimetallic actuator essentially consists of two metal strips fixed together. If the two metals have different expansivities, then as the temperature of the actuator changes, one element will expand more than the other, causing the device to bend out of the plane. This mechanical bending can then be used to actuate an electromechanical switch or be part of an electrical circuit itself, so that contact of the bimetallic device to an electrode causes a circuit to be made. Although in its simplest form a bimetallic actuator can be constructed from two flat pieces in metal, in practical terms a whole range of shapes are used to provide maximum actuation or maximum force during thermal cycling.

As a temperature measuring device, the bimetallic element, similar in design to that of the actuator above, can be used to determine the ambient temperature if the degree of bending can be measured. The advantage of such a system is that the amount of bending can be mechanically amplified to produce a large and hence easily measurable displacement.

The basic principle of a bimetallic actuator is shown in Figure 32.1. Here, two metal strips of differing thermal expansion are bonded together. When the temperature of the assembly is changed, in the absence
of external forces, the bimetallic actuator will take the shape of an arc. The total displacement of the actuator out of the plane of the metal strips is much greater than the individual expansions of the metallic elements. To maximize the bending of the actuator, metals or alloys with greatly differing coefficients of thermal expansion are normally selected. The metal having the largest thermal expansivity is known as the active element, while the metal having the smaller coefficient of expansion is known as the passive element. For maximum actuation, the passive element is often an iron–nickel alloy, Invar, having an almost zero thermal expansivity (actually between 0.1 and $1 \times 10^{-6} K^{-1}$, depending upon the composition). The active element is then chosen to have maximum thermal expansivity given the constraints of operating environment and costs.

In addition to maximizing the actuation of the bimetallic element, other constraints such as electrical and thermal conductivity can be made. In such cases, a third metallic layer is introduced, consisting of either copper or nickel sandwiched between the active and passive elements so as to increase both the electrical and thermal conductivity of the actuator. This is especially important where the actuator is part of an electrical circuit and needs to pass current in addition to being a temperature sensor.

**Linear Bimaterial Strip**

**Basic Equations**

The analysis of the stress distribution and the deflection of an ideal bimetallic strip was first deduced by Timoshenko [1], who produced a simple derivation from the theory of elasticity. Figure 32.2 shows the internal forces and moments that induce bending in a bimetallic strip followed by the ideal stress distribution in the beam. This theory is derived for bimetallic strips, but is equally applicable to bimaterial strips.

The general equation for the curvature radius of a bimetallic strip uniformly heated from $T_0$ to $T$ in the absence of external forces is given by [1]:

$$\frac{1}{R} - \frac{1}{R_0} = \frac{6(1+m)^2(\alpha_2 - \alpha_1)(T-T_0)}{t \left[ 3(1+m)^2 + (1+mn)(m^2 + 1/mn) \right]} \tag{32.1}$$

where $1/R_0$ = Initial curvature of the strip at temperature $T_0$  
$\alpha_1$ and $\alpha_2$ = Coefficients of expansion of the two elements: (1) low expansive material and (2) high expansive material  
$n$ = $E_1/E_2$, with $E_1$ and $E_2$ their respective Young's moduli  
$m$ = $t_1/t_2$, with $t_1$ and $t_2$ their respective thicknesses  
$t$ = $t_1 + t_2$ thickness of the strip

The width of the strip is taken as equal to unity.

Equation 32.1 applies for several strip configurations, including the simply supported strip and a strip clamped at one end (i.e., a cantilever). For a given configuration, the deflection of a strip can be determined by its relationship with curvature, $1/R$.

An example of a calculation of deflection is a bimetallic strip simply supported at its two ends. The initial curvature $1/R_0$ is assumed to be zero. Figure 32.3 shows the geometrical relationship between the radius $R$ of the strip and the deflection $d$ at its mid-point and is given by:

$$\left( R - t_2 \right)^2 = \left( R - d - t_2 \right)^2 + \left( \frac{L}{2} \right)^2 \tag{32.2}$$
Hence,

\[
\frac{1}{R} = \frac{8d}{L^2 + 4d^2 + 8dt_2} \quad (32.3)
\]

Making the assumption that the deflection and the thickness are less than 10% of the length of the strip (which is true in most practical cases) means the terms \(8dt_2\) and \(4d^2\) are therefore negligible and the expression reduces to:

\[
d = \frac{L^2}{8R} \quad (32.4)
\]

or

© 1999 by CRC Press LLC
If a 100-mm strip is composed of two layers of the same thickness (0.5 mm) with the high-expansive layer being made of iron (from Table 32.1, \( E_2 = 211 \text{ GPa} \) and \( \alpha_2 = 12.1 \times 10^{-6} \text{ K}^{-1} \)), the low-expansive layer made of Invar (from Table 32.1, \( E_1 = 140 \text{ GPa} \) and \( \alpha_1 = 1.7 \times 10^{-6} \text{ K}^{-1} \)), and the temperature increases from 20°C to 120°C, then the theoretical bending at the middle of the strip will be 1.92 mm.

As a second example, consider the calculation of the deflection of the free end of a bimetallic cantilever strip as illustrated in Figure 32.4. In this case, the geometrical relation is:

\[
d = L^2 \frac{3(1 + m)^2}{4t_1^2} \frac{3(1 + m)^2}{3(1 + m)^2 + (1 + m)(m^2 + 1/m)} (\alpha_2 - \alpha_1) (T - T_0)
\]  

(32.5)

FIGURE 32.3 Bending of a strip simply supported at its ends.

\[
d = L^2 \frac{3(1 + m)^2}{4t_1^2} \frac{3(1 + m)^2}{3(1 + m)^2 + (1 + m)(m^2 + 1/m)} (\alpha_2 - \alpha_1) (T - T_0)
\]  

Making the same assumptions as before, that is, \( d^2 \ll L^2 \) and \( dt_i \ll L^2 \), then the deflection of the free end is given by:

\[
d = \frac{L^2}{8R}
\]  

(32.7)
and combining this with Equation 32.1 yields:

\[ d = L^2 \frac{3(1 + m)^2}{t \left[ 3(1 + m)^2 + (1 + mn)(m^2 + 1/mn) \right]} \left( \alpha_2 - \alpha_1 \right) \left( T - T_0 \right) \]  

(32.8)

If an aluminum and silicon nitride bimaterial microcantilever as used for sensor research [2] is considered, then \( L = 200 \mu m \), \( t_1 = 0.6 \mu m \), \( t_2 = 0.05 \mu m \), \( E_1 = 300 \) GPa, \( E_2 = 70 \) GPa, \( \alpha_1 = 3 \times 10^{-6} \) K\(^{-1} \), \( \alpha_2 = 24 \times 10^{-6} \) K\(^{-1} \) (see Table 32.1). In this situation, a temperature difference of 1°C gives a theoretical deflection of the cantilever of 0.103 mm.

**Terminology and Simplifications**

For industrial purposes, bimetallic thermostatic strips and sheets follow a standard specification — ASTM [3] in the U.S. and DIN [4] in Europe. Important parameters involved in this specification are derived directly from the previous equations, in which simplifications are made based on common applications.

It can be seen that the magnitude of the ratio \( E_1/E_2 = n \) has no substantial effect on the curvature of the strip, and taking \( n = 1 \) implies an error less than 3%. Assuming again that the initial curvature is zero, Equation 32.1 can be simplified to:

\[ \frac{1}{R} = \frac{6m}{t(m+1)} \left( \alpha_2 - \alpha_1 \right) \left( T - T_0 \right) \]  

(32.9)

\(^a\) From Reference [13], Table A1 at 20°C.  
\(^b\) From Reference [13], Table A2 at 300K.  
\(^c\) From Goodfellow catalog 1995/1996 [14].
In most industrial applications involving bimetallic elements, the thicknesses of the two component layers are taken to be equal \((m = 1)\), thus Equation 32.6 becomes:

\[
\frac{1}{R} = \frac{3}{2} \left( \alpha_2 - \alpha_1 \right) \frac{T - T_0}{t} \quad (32.10)
\]

The constant \(\frac{3}{2} (\alpha_2 - \alpha_1)\) is known as flexivity in the U.S. and as specific curvature in Europe. Introducing the flexivity, \(k\), and rearranging Equation 32.10 gives:

\[
k = \frac{R}{T - T_0} \quad (32.11)
\]

Flexivity can be defined as “the change of curvature of a bimetal strip per unit of temperature change times thickness” [5]. The experimental determination of the flexivity for each bimetallic strip has to follow the test specifications ASTM B388 [3] and DIN 1715 [4]. The method consists of measuring the deflection of the midpoint of the strip when it is simply supported at its ends. Using Equation 32.4 derived above and combining with Equation 32.11 gives:

\[
k = \frac{8dt}{(T - T_0) L^2} \quad (32.12)
\]
Coming back to the second example of the calculation of the deflection (cantilever case), using Equation 32.10 and the same assumptions \((m = n = 1)\), Equation 32.7 becomes:

\[
d = \frac{kL^2}{2t} \left( T - T_0 \right)
\]  

(32.13)

In Europe, the constant \(a = \frac{dt}{(T - T_0)L^2} \) (theoretically equal to \(k/2\)) is called specific deflection and is measured following the DIN test specification from the bending of a cantilever strip. It can be noted that the experimental value differs from the theoretical value as it takes into account the effect of the external forces suppressing the cross-curvature where the strip is fastened (i.e., the theory assumes that the curvature is equal along the strip; whereas in reality, the fact that the strip is fastened implies that the radius is infinite at its fixed end).

Tables 32.2 and 32.4 present a selection of bimetallic elements following ASTM and DIN standards, respectively. Flexivity (or specific curvature), linear temperature range, maximum operating temperature, and specific deflection (DIN only) are given. The details of the chemical composition of these elements are specified in Tables 32.3 and Table 32.5.

### Industrial Applications

The mechanical thermostat finds a wide range of applications in temperature control in industrial processes and everyday life. This widespread use of thermostats is due to the discovery of Invar, a 36% nickel alloy that has a very low thermal expansion coefficient, and was so named because of its property of invariability [6].

There are two general classes of bimetallic elements based on their movement in response to temperature changes. Snap-action devices jump from one position to another at a specific temperature depending on their design and construction. There are numerous different shapes and sizes of snap-action elements and they are typically ON/OFF actuators. The other class of elements, creep elements, exhibit a gradual change in shape in response to a change in temperature and are employed in temperature gauges and other smooth movement applications. Continuous movement bimetals will be considered first. A linear configuration was covered previously, so the discussion will focus on coiled bimetallic elements.

### Spiral and Helical Coil Configurations

For industrial or commercial measurements, a spiral or helical coil configuration is useful for actuating a pointer on a dial as the thermal deflection is linear within a given operating range. Linearity in this
case means that the deflection does not vary by more than 5% of the deflection, as calculated from the flexivity [4]. The basic bimaterial ideas from the previous section still apply, with some additional equations relating the movement of a bimetal coil to a change in temperature. As in the previous section, standard methods for testing the deflection rate of spiral and helical coils exist and can be found in [7]. The following equations have been taken from the Kanthal Thermostatic Bimetal Handbook [8], with some change in notation. The angular rotation of a bimetal coil is given by (see Figure 32.5):

From DIN 1715 Standard [4].
where \( L \) = length of the strip
\( R_0 \) and \( R \) = initial and final bending radii (assumed to be constant along the strip), respectively.

In terms of the specific deflection \( a \), this can be written as:

\[
\theta = \left( \frac{1}{R} - \frac{1}{R_0} \right) L \tag{32.14}
\]

where \( t \) = thickness of the device
\( T_0 \) and \( T \) = initial and final temperatures, respectively.

An example would be a helical bimetal coil inside a steel tube with one end of the coil fixed to the end of the tube and the other connected to a pointer. The accuracy of a typical commercial product is 1% to 2% of full-scale deflection with an operating range of 0°C to 600°C [9].

If a change in temperature is required to both move a pointer and produce a driving force, then the angular rotation is reduced and is given by:

\[
\theta = \frac{2aL(T - T_0)360}{t} \frac{1}{2\pi} \tag{32.15}
\]

where \( w \) = width of the element
\( r \) = distance from the center of the coil to the point of applied force, \( F \)

This can be rewritten as:

\[
T - T_0 = \frac{\theta r}{2aL} \frac{2\pi}{360} + \frac{6(F - F_0)r}{wtEa} \tag{32.17}
\]
where the first term represents the temperature associated with the angular rotation of the strip and the second term represents the temperature associated with the force generated by the strip. In general, the strip is designed so that the two are equal, as this leads to the minimum volume for the strip and consequently less weight and cost for the device.

Finally, if the coil is prevented from moving then the change in torque is given by

\[
\tau = \frac{1}{6}wT^2\theta_0 (T - T_0)
\]

(32.18)

**Example:** Consider a bimetal element that measures a temperature change from 20°C to 100°C and moves a lever 50 mm away with a force of 1 N. A dial reading range of 180° is required.

Choosing thermostatic bimetal TM2 gives the largest deflection per degree temperature change and TM2 meets the operating temperature requirements. Both a force and a movement are involved, so use Equation 32.7. Choosing each term equal to half the temperature change gives the minimum volume for the strip as:

\[
\frac{1}{2} (T - T_0) = \frac{\theta_t}{2aL} \frac{2\pi}{360} = \frac{6(F - F_0)r}{wt^2Ea}
\]

(32.19)

Selecting a thickness of 1.0 mm and using a specific deflection of \(19 \times 10^{-6} \, ^\circ C^{-1}\) (\(a = k / 2\) from Table 32.2) gives a width of 29 mm. Similarly, the length of the bimetal strip is obtained from the second term in the equality, giving \(L = 2.1\) m.

**Snap-Action Configurations**

Snap-action bimetal elements are used in applications where an action is required at a threshold temperature. As such, they are not temperature measuring devices, but rather temperature-activated devices. The typical temperature change to activate a snap-action device is several degrees and is determined by the geometry of the device (Figure 32.6). When the element activates, a connection is generally made or broken and in doing so, a gap between the two contacts exists for a period of time. For a mechanical system, there is no problem; however, for an electrical system, the gap can result in a spark that can lead to premature aging and corrosion of the device. The amount and duration of spark is reduced by having the switch activate quickly, hence the use of snap-action devices.

Snap-action elements also incorporate a certain amount of hysteresis into the system, which is useful in applications that would otherwise result in an oscillation about the set-point. It should be noted, however, that special design of creep action bimetals can also lead to different ON/OFF points, such as in the reverse lap-welded bimetal [8].

**Sensitivity and Accuracy**

Modern techniques are more useful where sensitivity and accuracy are concerned for making a temperature measurement; however, bimetals find application in commercial and industrial temperature control where an action is required without external connections. Evidently, geometry is important for bimetal
systems as the sensitivity is determined by the design, and a mechanical advantage can be used to yield a large movement per degree temperature change. A demonstration of sensitivity using a helical coil was made by Huston [10] that gave 6 in. (15.2 cm) deflection per degree in their measurement system — yielding a sensitivity of 0.01°F per 1/16 in. (0.0035°C mm⁻¹). Huston also demonstrated a repeatable accuracy of 0.05°F (0.027°C) based on the use of a 0.1°F (0.056°C) accuracy calibration instrument.

The operating range for many bimetals is quite large; however, there is a range over which the sensitivity is a maximum. A bimetal element is generally chosen to operate in this range and specific details are provided by manufacturers in their product catalogs. Of particular note is that, despite extended thermal cycling, bimetal strips reliably return to the same position (i.e., show no hysteresis) at a given temperature and are very robust as long as they are not subjected to temperatures outside their specified operating range.

Advanced Applications

Thermostatic valves are a ready and robust means of measuring temperature and controlling heating and cooling in industrial settings. The basic designs have been around for many years and are the mainstay of many commercial temperature-control systems. New applications of bimaterials are being found in microactuators and microsensors.

Besides operating as temperature-measuring instruments, bimaterial devices can be used for a variety of applications where temperature is the controlling or triggering phenomenon, or indeed, other material properties are inferred from the temperature response. One such example is a nickel–silicon actuator developed by engineers at HP labs in Palo Alto, CA; the actuator operates by heating a thin nickel resistor on the silicon side of a bilayer device[11]. Both the silicon and nickel layers expand due to heating; however, the nickel layer expands more, thereby curling the device, which leads to the actuation of a tiny valve. The device can control gas flow rates from 0.1 to 600 standard cm³ per minute with pressures ranging from 5 psi to 200 psi (34.5 kPa to 1379 kPa).

The use of micromachined thermal sensors compatible with modern silicon integrated circuit fabrication methods has recently received significant attention. One way of achieving highly sensitive thermal measurements is by using micromechanical bimetallic cantilevers and measuring the deflection as a result of thermal fluctuations. Rectangular or triangular cantilevers, typically 100 μm long made of silicon or silicon nitride, are coated with a thin high-expansive metallic layer (e.g., aluminum or gold). Precise measurement of the deflection of the end of the cantilever is achieved using an optical sensing arrangement commonly used in atomic force microscopes. The micromechanical nature of the cantilever-based sensor leads to significant advantages in the absolute sensitivity achievable. In this way, the device is capable of measuring temperature, heat, and power variations of 10⁻³ K, 150 fJ, or 100 pW, respectively [2]. In addition to their use as thermal sensors, the bimetallic cantilever systems have been used to investigate physical phenomena where heat is produced by the sample. Examples include photothermal spectroscopy studies of amorphous silicon [2] and the observation of oscillations in the catalyzed reaction of hydrogen and oxygen on platinum [12]. Thus, bimaterial sensors are becoming an increasingly important area of development.

Defining Terms

**Linear coefficient of thermal expansion:** The change in length of a material per degree change in temperature expressed as a fraction of the total length (ΔL/L).

**Flexivity:** The change in radius of curvature of a bimaterial per degree change in temperature times the width of the element (See Equation 32.11).

**Specific curvature:** The European term for flexivity.

**Specific deflection:** Theoretically equal to half the flexivity. Specific deflection is measured by mounting the test element as a cantilever — supported at one end and free to move at the other.

32.2 Resistive Thermometers

*Jim Burns*

Introduction to Resistance Temperature Detectors

One common way to measure temperature is by using Resistive Temperature Detectors (RTDs). These electrical temperature instruments provide highly accurate temperature readings: simple industrial RTDs used within a manufacturing process are accurate to ±0.1°C, while Standard Platinum Resistance Thermometers (SPRTs) are accurate to ±0.0001°C.

The electric resistance of certain metals changes in a known and predictable manner, depending on the rise or fall in temperature. As temperatures rise, the electric resistance of the metal increases. As temperatures drop, electric resistance decreases. RTDs use this characteristic as a basis for measuring temperature.

The sensitive portion of an RTD, called an element, is a coil of small-diameter, high-purity wire, usually constructed of platinum, copper, or nickel. This type of configuration is called a wire-wound element. With thin-film elements, a thin film of platinum is deposited onto a ceramic substrate.

Platinum is a common choice for RTD sensors because it is known for its long-term stability over time at high temperatures. Platinum is a better choice than copper or nickel because it is chemically inert, it withstands oxidation well, and works in a higher temperature range as well.

In operation, the measuring instrument applies a constant current through the RTD. As the temperature changes, the resistance changes and the corresponding change in voltage is measured. This measurement is then converted to thermal values by a computer. Curve-fitting equations are used to define
this resistance vs. temperature relationship. The RTD can then be used to determine any temperature from its measured resistance.

A typical measurement technique for industrial thermometers involves sending a constant current through the sensor (0.8 mA to 1.0 mA), and then measuring the voltage generated across the sensor using digital voltmeter techniques. The technique is simple and few error-correcting techniques are applied.

In a laboratory where measurement accuracies of 10 ppm or better are required, specialized measurement equipment is used. High-accuracy bridges and digital voltmeters with special error-correcting functions are used. Accuracies of high-end measurement equipment can reach 0.1 ppm (parts per million). These instruments have functions to compensate for errors such as thermoelectric voltages and element self-heating.

In addition to temperature, strain on and impurities in the wire also affect the sensor’s resistance vs. temperature characteristics. The Matthiessen rule states that the resistivity ($\rho$) of a metal conductor depends on temperature, impurities, and deformation. $\rho$ is measured in ($\Omega$ cm):

$$\rho_{\text{total}} = \rho_{\text{temperature}} + \rho_{\text{impurities}} + \rho_{\text{deformation}}$$  \hspace{1cm} (32.20)

Proper design and careful material selection will minimize these effects so that resistivity will only vary with a change in temperature.

**Resistance of Metals**

Whether an RTD’s element is constructed of platinum, copper, or nickel, each type of metal has a different sensitivity, accuracy, and temperature range. Sensitivity is defined as the amount of resistance change of the sensor per degree of temperature change. Figure 32.7 shows the sensitivity for the most common metals used to build RTDs.

Platinum, a noble metal, has the most stable resistance-to-temperature relationship over the largest temperature range $-184.44^\circ$C ($-300^\circ$F) to $648.88^\circ$C ($1200^\circ$F). Nickel elements have a limited temperature range.

**FIGURE 32.7** Of the common metals, nickel has the highest sensitivity.
range because the amount of change in resistance per degree of change in temperature becomes very nonlinear at temperatures above 300°C (572°F). Copper has a very linear resistance-to-temperature relationship. However, copper oxidizes at moderate temperatures and cannot be used above 150°C (302°F).

Platinum is the best metal for RTD elements for three reasons. It follows a very linear resistance-to-temperature relationship; it follows its resistance-to-temperature relationship in a highly repeatable manner over its temperature range; and it has the widest temperature range among the metals used to make RTDs. Platinum is not the most sensitive metal; however, it is the metal that offers the best long-term stability.

The accuracy of an RTD is significantly better than that of a thermocouple within an RTD’s normal temperature range of –184.44°C (–300°F) to 648.88°C (1200°F). RTDs are also known for high stability and repeatability. They can be removed from service and recalibrated for verifiable accuracy and checked for any possible drift.

**Who Uses RTDs? Common Assemblies and Applications**

Different applications require different types of RTDs. A direct-immersion Platinum Resistance Thermometer (PRT) and a connection head can be used for low-velocity pipelines, tanks, or air temperature measurement. A spring-loaded PRT, thermowell, and connection head are often used in pipelines or storage tanks. An averaging temperature element senses and measures temperatures along its entire sheath, which can range from 1 to 20 m in length. A heavy-duty underwater temperature sensor is designed for complete submersion under rivers, cooling ponds, or sewers. These are just a few examples of RTD configurations and applications.

**Overview of Platinum RTDs**

There are three main classes of Platinum Resistance Thermometers (PRTs): Standard Platinum Resistance Thermometers (SPRTs), Secondary Standard Platinum Resistance Thermometers (Secondary SPRTs), and Industrial Platinum Resistance Thermometers (IPRTs). Table 32.6 presents information about each.

**Temperature Coefficient of Resistance**

Each of the different metals used for sensing elements (platinum, nickel, copper) has a different amount of relative change in resistance per unit change in temperature. A measure of a resistance thermometer’s sensitivity is its temperature coefficient of resistance. It is defined as the element’s change in resistance per degree C change in temperature per ohm of sensor resistance over the range of 0°C to 100°C.

The alpha value is the average change in resistance per degree C per ohm resistance. The actual change in resistance per degree C per ohm is largest at –200°C and decreases steadily as the use temperatures increase.

</table>

*I = immersion; A = air; S = surface.*
The units for the coefficient are $\Omega/\Omega^{-1} \cdot ^\circ C^{-1}$. This is called the alpha value and is commonly denoted by the Greek letter $\alpha$. The larger the temperature coefficient, the greater the change in resistance for a given change in temperature. Of the commonly used RTD metals, nickel has the highest temperature coefficient, 0.00672, while that of copper is 0.00427. The $\alpha$ value of the sensor is calculated using the equation:

$$\alpha = \frac{R_{100} - R_0}{100^\circ C \times R_0}$$

(32.21)

where $R_0$ = the resistance of the sensor at 0$^\circ C$

$R_{100}$ = the resistance of the sensor at 100$^\circ C$

Three primary temperature coefficients are specified for platinum:

1. ITS-90, the internationally accepted temperature scale, requires a minimum temperature coefficient of 0.003925 for SPRTs. This is achieved using high-purity wire (99.999% or better) wound in a strain-free configuration.

2. With reference-grade platinum wire used in industrial elements, the temperature coefficient is 0.003902.

3. IEC 751 [1] and ASTM 1137 [2] have standardized the temperature coefficient of 0.0038500 for platinum.

**RTD Construction**

Standard Platinum Resistance Thermometers (SPRTs), the highest-accuracy platinum thermometers, are fragile and used in laboratory environments only (Figure 32.8). Fragile materials do not provide enough strength and vibration resistance for industrial environments. SPRTs feature high repeatability and low drift, but they cost more because of their materials and expensive production techniques.

SPRT elements are wound from large-diameter, high-purity platinum wire. Internal leadwires are usually made from platinum and internal supports from quartz or fused silica. SPRTs are used over a very wide range, from $-200^\circ C$ ($-328^\circ F$) to above 1000$^\circ C$ ($1832^\circ F$). For SPRTs used to measure temperatures up to 660$^\circ C$ (1220$^\circ F$), the ice point resistance is typically 25.5 $\Omega$. For high-temperature thermometers, the ice point resistance is 2.5 $\Omega$ or 0.25 $\Omega$. SPRT probes can be accurate to $\pm 0.001^\circ C$ (0.0018$^\circ F$) if properly used.

Secondary Standard Platinum Resistance Thermometers (Secondary SPRTs) are also intended for laboratory environments (Figure 32.9). They are constructed like the SPRT, but the materials are less expensive, typically reference-grade, high-purity platinum wire, metal sheaths, and ceramic insulators. Internal leadwires are usually a nickel-based alloy. The secondary grade sensors are limited in temperature...
range — –200°C (–328°F) to 500°C (932°F) — and are accurate to ±0.03°C (±0.054°F) over their temperature range.

Secondary standard thermometers can withstand some handling, although they are still quite strain-free. Rough handling, vibration, and shock will cause a shift in calibration. The nominal resistance of the ice point is most often 100Ω. This simplifies calibration procedures when calibrating other 100-Ω RTDs. The temperature coefficient for secondary standards using reference-grade platinum wire is usually 0.00392 Ω/°C or higher.

Industrial Platinum Resistance Thermometers (IPRTs) are designed to withstand industrial environments and are almost as durable as thermocouples (Figure 32.10). IEC 751 [1] and ASTM 1137 [2] standards cover the requirements for industrial platinum resistance thermometers. The most common temperature range is –200°C (–328°F) to 500°C (932°F). Standard models are interchangeable to an accuracy of ±0.25°C (±0.45°F) to ±2.5°C (±4.5°F) over their temperature range.

Several element designs are available for different applications. One common configuration is the wirewound element (Figure 32.11). This durable design was developed as a substitute for the fragile SPRT. The small platinum sensing wire (usually within 7 to 50 µm (0.0003 in. to 0.002 in. diameter) is noninductively wound around a cylindrical ceramic mandrel, and usually covered with a thin layer of material that provides electrical insulation and mechanical protection. Because the sensing element wire is firmly supported, it cannot expand and contract as freely as the SPRT’s relatively unsupported platinum wire. This type of element offers higher durability than SPRTs and secondary standards, and very good accuracy for most industrial applications.

In another wirewound design, the coil suspension, a coil of fine platinum wire is assembled into small holes in a cylindrical ceramic mandrel (Figure 32.12). The coils are supported by ceramic powder or cement, and sealed at both ends. When ceramic powder is loosely packed in the bores of the mandrel,
the element can expand and contract freely. This reduces the effects of strain on the resistance characteristics, resulting in very high accuracy and stability for use in secondary temperature standards and docile industrial applications (with little or no vibration or shock). Recent improvements in ceramic materials give the sensing coil more stability — it will be capable of maintaining accuracies of 0.03°C after thousands of hours at temperatures of 500°C. These ceramic powders support the coils in the mandrel bores and hold them firmly in place with minimum strain.

Thin-film elements are extremely small, often less than 1.6 mm (1/16 in.) square (Figure 32.13). They are manufactured by similar techniques employed to make integrated circuits. First, a thin film of platinum is deposited onto a ceramic substrate. Some manufacturers use photolithography to etch the deposited platinum, leaving the element pattern on the ceramic substrate. Then, the element’s surfaces are covered with glass material to protect the elements from humidity and contaminants.
The temperature range of thin film platinum elements is \(-50^\circ C\) \((-58^\circ F)\) to \(400^\circ C\) \((752^\circ F)\); accuracy is from \(0.5^\circ C\) \((0.9^\circ F)\) to \(2.0^\circ C\) \((3.6^\circ F)\). The most common thin-film element has a 100-\(\Omega\) ice point resistance and a temperature coefficient of \(0.00385^\circ C\).

Thin-film RTDs can be extremely durable if the small-diameter leadwires and the thin element are properly protected. The accuracy and stability might not be as good as some wirewound elements due to hysteresis, long-term stability errors, and self-heating errors.

**Self-heating Errors**

The current that measures sensor resistance also heats the sensor. This is known as \(I^2R\) heating or Joule heating. Because of this effect, the sensor’s indicated temperature is somewhat higher than the actual temperature. This inconsistency is commonly called self-heating error. Self-heating errors, which are dependent on the application, can range from negligible values to \(1^\circ C\). The greatest heating errors occur because of poor heat transfer between the sensing element and application, or excessive current used in measuring resistance.

The following are methods for reducing the self-heating error.

1. Minimize the power dissipation in the sensor. There is a tradeoff between the signal level and the self-heating of the sensor. Typically, 1 mA of current is used as the sensing current.
2. Use a sensor with a low thermal resistance. The lower the thermal resistance of the sensor, the better the sensor can dissipate the \(I^2R\) power and the lower the temperature rise in the sensor. Small time constants indicate a sensor with a low thermal resistance.
3. Maximize thermal contact between the sensor and the application.

**Calibration**

Testing programs are essential to verify the accuracy of PRTs. Some IPRTs are factory-calibrated to a temperature such as at the ice point, but PRT users might want to calibrate them at other temperatures, depending on their application.

The calibration results can be compared to prior calibrations from the same instrument. This will determine if it is necessary to repair or replace the instrument, or if calibration is required more often.

Since frequent repairs and recalibration are usually costly, purchasers and specifiers of PRTs might want to investigate various RTDs before installation by referring to ASTM Standard #E1137-95 [2], published by The American Society for Testing and Materials (ASTM).

**Frequency.** An RTD’s stability depends on its working environment. High temperatures can cause drift and contamination of the platinum wire. The higher the temperature, the faster the drift occurs. Below \(400^\circ C\), the high-temperature drift is not a significant problem, but temperatures reaching \(500^\circ C\) to \(600^\circ C\) are the most significant causes of drift — up to several degrees per year. Severe shock can damage a sensor instantly and cause failure. Shock, vibration, and rough handling will put strains in the platinum wire and change its characteristics, and ultimately damage the entire unit. If a sensor is not properly sealed, humidity can get into the sensor and cause some problems with the insulation resistance. Since the water in humidity is conductive, it will get between the lead wires and the sensing element, and basically shunt off the resistance of the element’s wires. Under extreme operating conditions, a sensor should be calibrated on a monthly or bimonthly basis. If five or more calibrations are completed without a significant change, then the time between calibrations can be doubled; at least once a year is recommended, however.

**Techniques.** Two common calibration methods are the fixed point method and the comparison method.

*Fixed point calibration,* used for the highest accuracy calibrations, uses the triple point, freezing point or melting point of pure substances such as water, zinc, tin, and argon to generate a known and repeatable temperature (*Figure 32.14*). The fixed point cells are sealed to prevent contamination and to prevent atmospheric conditions from affecting the cell’s temperature. These cells allow the user to reproduce actual conditions of the ITS-90 temperature scale.
Fixed point calibrations provide extremely accurate calibrations (within ±0.001°C), but the cells are time-consuming to use and can only accommodate one sensor at a time. For this reason, they are not widely used in calibrating industrial sensors. Each fixed point cell has a unique procedure for achieving the fixed point.

A generalized procedure for fixed point calibration is as follows:

1. Prepare the cell. Different procedures exist for each fixed point.
2. Insert the thermometer to be calibrated.

FIGURE 32.14 Fixed point calibration uses the triple point, freezing point, or melting point of water, zinc, tin, and argon.
3. Allow the system to stabilize. Stabilization times depend on thermometer/fixed point cells. Usually, 15 to 30 min is sufficient.
4. Measure the resistance of the thermometer. For the highest accuracy measurements, special resistance bridges are used. They have accuracies in the range of 10 ppm to 0.1 ppm.

A common fixed point calibration method for industrial-grade probes is the ice bath. The equipment is inexpensive, easy to use, and can accommodate several sensors at once. The ice point is designated as a secondary standard because its accuracy is \( ±0.005°C \) \( (±0.009°F) \), compared to \( ±0.001°C \) \( (±0.0018°F) \) for primary fixed points.

In comparison calibrations, commonly used with secondary SPRTs and industrial RTDs, the thermometers being calibrated are compared to calibrated thermometers by means of an isothermal bath whose temperature is uniformly stable (Figure 32.15). Unlike fixed point calibrations, comparisons can be made at any temperature between \(-100°C \) \( (−148°F) \) and \( 500°C \) \( (932°F) \). This method might be more cost-effective since several sensors can be calibrated simultaneously with automated equipment.

These isothermal baths, electrically heated and well-stirred, use silicone oils as the medium for temperatures ranging from \(-100°C \) \( (−148°F) \) to \( 200°C \) \( (392°F) \), and molten salts for temperatures above \( 200°C \) \( (392°F) \). At temperatures above \( 500°C \) \( (932°F) \), air furnaces or fluidized beds are used, but are significantly less uniformly stable.

The procedure for comparison calibration is as follows:

1. Insert the standard thermometer and thermometers being calibrated into the bath.
2. Allow the bath to stabilize.
3. Measure the resistance of the standard to determine the temperature of the bath.
4. Measure the resistance of each thermometer under calibration.

**Deriving the resistance vs. temperature relationship of a PRT.** After determining the PRT’s resistance, the calibration coefficients can be determined. By plugging these values into an equation, temperature...
from any measured resistance can be derived. The two most common curve-fitting techniques are the ITS-90 and Callendar–Van Dusen equations.

On January 1, 1990, the International Temperature Scale of 1990 (ITS-90) became the official international temperature scale [3]. ITS-90 extends upward from 0.65 K (–272.5°C or –458.5°F) and defines temperatures of 0.65 K (0.65°C above absolute zero) and up by fixed points (see Table 32.7).

Two reference functions are used to define the temperature coefficient for an ideal SPRT: one for temperatures below 0°C and the other for temperatures above 0°C. When a PRT is calibrated on the ITS-90, the coefficients determined in the calibration are used to describe a deviation function that represents the difference between the resistance of the standard PRT and the reference function at all temperatures within the range. Using the calibration coefficients and the deviation functions, the SPRT can be used to determine any temperature from its measured resistance. Because ITS-90 equations are complex, computer software is necessary for accurate calculations.

ITS-90 affects:

- Standards and temperature calibration laboratories
- Users of standard and secondary SPRTs with traceability to standards laboratories
- Users of temperature measurement and control systems within companies concerned with verifiable total quality management

The National Institute for Standards and Technology (NIST) has published Technical Note 1265, Guidelines for Realizing the International Temperature Scale of 1990 [4]. Not all PRT users need to follow the complex equations and computer programs associated with ITS-90. As a rule of thumb: if the minimum required uncertainty of measurement is less than 0.1°C, one probably will want to use ITS-90. For uncertainty of measurements greater than 0.1°C, the effect of the change in scales is relatively small and one will not be affected.

Callendar–Van Dusen equations are interpolation equations that describe the temperature vs. resistance relationship of industrial PRTs. These simple-to-use second- and fourth-order equations can be programmed

easily into many electronic controllers. The equation for the temperature range of 0°C (32°F) to 850°C (1562°F) is:

\[ R(t) = R_0 \left(1 + At + Bt^2 \right) \]  

(32.22)

For the temperature range –200°C (–392°F) to 0°C (32°F):

\[ R(t) = R_0 \left[ 1 + At + Bt^2 + C(t-100)t^3 \right] \]  

(32.23)

where 

- \( R(t) \) = Resistance of the PRT at temperature \( t \)
- \( t \) = Temperature in °C
- \( R_0 \) = Nominal resistance of the PRT at 0°C
- \( \alpha, \delta, \beta \) = Calibration coefficients

To determine the temperature from a measured resistance, a different set of equations and calibration coefficients is required. For temperatures greater than 0°C (measured resistances greater than the known ice point resistance of the PRT):

\[ t(°C) = \left[ \left( R_t - R_0 \right)/\alpha R_0 \right] + \delta \left[ \left( t/100 \right) - 1 \right] \left( t/100 \right) \]  

(32.24)

For temperatures less than 0°C (measured resistances less than the known ice point resistance of the PRT):

\[ t(°C) = \left[ \left( R_t - R_0 \right)/\alpha R_0 \right] + \delta \left[ \left( t/100 \right) - 1 \right] \left( t/100 \right) + \beta \left[ \left( t/100 \right) - 1 \right] \left( t/100 \right)^3 \]  

(32.25)

where 

- \( t \) = Temperature to be calculated
- \( R(t) \) = Measured resistance at unknown temperature
- \( R_0 \) = Resistance of the sensor at 0°C
- \( \alpha, \delta, \beta \) = Coefficients

To correctly determine the temperature from a given resistance with these equations, one must iterate the equations a minimum of five times. After each calculation, the new value of temperature \( t \) is plugged back into the equations. The calculated temperature value will converge on its true value. After five iterations, the calculated temperature should be within ±0.001°C of the true value.

For industrial sensors, an alternative method would be to use nonlinear least squares curve fits to produce the temperature/resistance relationship. However, these methods should not be used for secondary and primary level thermometers as they cannot sufficiently match the defined ITS-90 scale. Curve fitting errors of up to 0.05°C are possible.

Usage of RTDs Today

Throughout the industry, usage of RTDs is increasing for many reasons. With the advent of the computer age, industries recognize the need for better temperature measurement, and an electrical signal to accompany advances in computerized process instrumentation. RTDs produce an electrical signal; and because of automatic control in industrial plants, it makes it simpler and easier to interface with process controllers. With the focus on reengineering, companies are searching for ways to improve processes. Improved temperature measurement and control is one good way to save energy, reduce material waste, reduce expenses and improve overall operating efficiencies.

Governmental regulations are another reason why RTDs are gaining popularity. In the pharmaceutical industry, the FDA [5] requires validation; among them the verification that temperature measurement is accurate. New regulations are currently being written for the food industry as well [6].
The growing worldwide acceptance of ISO 9000 standards has forced companies to calibrate their temperature measurement systems and instrumentation. In addition, the calibration must be documented, and must be traceable to a recognized national, legal standard.

RTDs are safer for the environment. With mercury thermometers, disposal of mercury is a problem. In many industries, the mere presence of mercury thermometers presents a risk.

**Examples of Advanced Applications for Critical Temperature Measurement**

RTD technology allows for custom design in a wide range of applications and industries. In many of these cases, the RTD becomes an integral part of an advanced application when temperature is critical.

Power plants use RTD sensors to monitor fuel and coolant temperatures entering and exiting heat exchangers. Accurate temperature measurement is also critical for nuclear power plants to perform pressure leak tests on the containment vessel surrounding the reactor core.

Microprocessor manufacturers require precise temperature control throughout their clean room areas. Air temperature is critical to production; many temperature measurement points need to be accurate ±0.028°C within (±0.05°F). To achieve this, an RTD is calibrated with a temperature transmitter. This matched pair ensures the highest level of system accuracy and eliminates the interchangeability error of the RTD.

**The Future of RTD Technology**

The future of RTD technology is driven by end-user needs and unsolved problems. For example, the need for high-temperature industrial RTDs exists for applications above 600°C (1200°F). In order to function at high temperatures, the RTD’s platinum element must be protected from contamination. However, the sheath material can be a problem because, at high temperatures, it will react with the oxygen in the air and give off metal particles that can attach themselves to the platinum.

RTDs must be mechanically strong enough to survive higher temperatures as well. A high-temperature industrial RTD would require a thermally resistant sheath, perhaps Inconel 600. In addition, sensor components must be designed and manufactured to resist ultra-high temperatures. Some RTDs are specified to operate above 600°C (1200°F), but when tested, are not always reliable. Drift and nonrepeatability are problem areas that are in need of further attention.

Advances in RTD calibration provide significant improvements for temperature measurement and control. New measurement technologies combined with powerful computational techniques, have simplified the calibration process and made it more reliable.

Another current area of growth is in-house calibration and calibration baths. Governmental validation requirements and ISO-9000 standards are the driving forces in this area. Because third-party calibration services are expensive, companies want to be more productive and more cost-efficient. Wong [7] discusses the benefits of setting up an in-house calibration lab in addition to traceability concepts. Traceability refers to an unbroken chain of comparisons, linking the temperature measurement to a recognized national, legal standard. In the U.S., this national standard is maintained by the National Institute of Standards and Technology (NIST). All RTD manufacturers, laboratories, and calibration labs must adjust their standards to meet NIST standards.

**Defining Terms**

**Accuracy:** The degree of agreement between an actual measurement and its reference standard.

**Alpha (α):** The temperature coefficient of resistance of a PRT over the range 0°C to 100°C. For example, $\alpha$ for a standard platinum resistance thermometer (SPRT) is 0.003925.

**Calibrate:** To check, adjust or determine an RTD’s accuracy by comparing it to a standard.

**DIN (Deutsche Industrial Norm):** A German organization that develops technical, scientific, and dimensional standards that are recognized worldwide.

**Error:** The difference between a correct value and the actual reading taken.
Primary Standard (or Standard PRT): A platinum resistance thermometer that meets the requirements for establishing calibrations according to the ITS-90. This highly accurate instrument is intended for laboratory environments and is accurate to 0.001°C.

Reliability: Used to designate precision for measurements made within a very restricted set of conditions.

Repeatability: The ability to give the same measurement under repeated, matching conditions.

Stability: The state of being resistant to change or deterioration.

Sensitivity: The amount of resistance change of the sensor per degree temperature change.

32.3 Thermistor Thermometers

Meyer Sapoff

A thermistor is a thermally sensitive resistor whose primary function is to exhibit a change in electric resistance with a change in body temperature. Unlike a wirewound or metal film resistance temperature detector (RTD), a thermistor is a ceramic semiconductor. An RTD exhibits a comparatively low temperature coefficient of resistance on the order of 0.4 to 0.5% °C⁻¹. Depending on the type of material system used, a thermistor can have either a large positive temperature coefficient of resistance (PTC device) or a large negative temperature coefficient of resistance (NTC device).

Two types of PTC thermistors are available. Silicon PTC thermistors rely on the bulk properties of doped silicon and exhibit resistance–temperature characteristics that are approximately linear. They have temperature coefficients of resistance of about 0.7 to 0.8% °C⁻¹. The most common application of silicon PTC thermistors is compensation of silicon semiconductor devices and circuits [1]. The materials used for switching-type PTC thermistors are compounds of barium, lead, and strontium titanates. Figure 32.16 shows the resistance–temperature characteristic of a typical switching-type PTC thermistor [2]. At low temperatures, from below 0°C to \( R_{\text{min}} \), the resistance value is low, and \( R_T \) vs. \( T \) exhibits a small negative temperature coefficient of resistance on the order of −1% °C⁻¹. As the temperature increases, the temperature coefficient of resistance becomes positive and the resistance begins to rise. At a threshold or switching temperature, the rate of rise becomes very rapid and the PTC characteristic becomes very steep. Within its switching range, the temperature coefficient of resistance can be as high as 100% °C⁻¹ and the device exhibits a high resistance value. At temperatures above the switching range, the resistance reaches a maximum value beyond which the temperature coefficient becomes negative again. The switching temperature can be varied between 80°C and 240°C by altering the chemical composition of the ceramic. Typical applications for switching-type PTC thermistors are over-temperature protection, current limiting, and self-regulated heating. The temperature coefficient of resistance of a unit used as a heating element typically is about 25% °C⁻¹ at a switching temperature of 240°C [1, 2].

NTC thermistors consist of metal oxides such as the oxides of chromium, cobalt, copper, iron, manganese, nickel, and titanium. Such units exhibit a monotonic decrease in electric resistance with an
increase in temperature. The resistance–temperature characteristics of NTC thermistors are nonlinear and approximate the characteristics exhibited by intrinsic semiconductors for which the temperature dependence of resistance is due to the excitation of carriers across a single energy gap. As such, the logarithm of resistance of an NTC thermistor is approximately a linear function of its inverse absolute temperature. Below room temperature, the slope of the function decreases and the thermistor behaves more like an extrinsic semiconductor. The actual conduction mechanism is comparable to the “hopping” mechanism observed in ferrites and manganites that have a spinel crystal structure. Conduction occurs when charge carriers hop from one ionic site in the spinel lattice to an adjacent site. Such hopping can occur when ions of the same element, with valences differing by 1, are present on equivalent lattice sites.

Because of its nonlinear resistance–temperature characteristic, the temperature coefficient of resistance of an NTC thermistor changes with temperature. Depending on the material system used, the temperature coefficient at 25°C typically is in the range of –3 to –5% °C⁻¹. At –60°C, it is in the range of –6.4 to –11.3% °C⁻¹; and at 100°C, it varies between –2.1 and –3.7% °C⁻¹. The corresponding resistance ratios with respect to 25°C, R₉/R₂₅, are 41 to 228 at –60°C and 0.13 to 0.03 at 100°C. The slope of the log R vs. 1/T characteristic β is relatively constant. The material systems for which the above data are presented exhibit β values of 2930 to 5135 K over the range of 25 to 125°C [1].

Although the resistance–temperature characteristic of an NTC thermistor is nonlinear, it is possible to achieve good linearity of the conductance–temperature and resistance–temperature characteristics using thermistor–resistor networks. The use of a resistor in series with a thermistor results in a linear conductance network, such as a voltage divider. The current obtained in response to a voltage applied to the network is linear with temperature. Consequently, the output of the voltage divider (voltage across the resistor) is linear with temperature. The parallel combination of a resistor and thermistor is a linear resistance network. Techniques exist for optimizing the linearity of single thermistor networks [3, 4].
Such networks exhibit S-shaped curves for their voltage–temperature or resistance–temperature characteristics. For temperature spans of 20°C to 30°C, the maximum deviation is small between any point on the curve and the best straight-line approximation of the curve. As the span increases beyond 30°C, the maximum deviation from linearity increases rapidly from about 0.15°C for a 30°C span to 0.7°C for a 50°C span. Using a two-thermistor network, a maximum linearity deviation of 0.22°C can be obtained over a range of 0°C to 100°C, as compared with a 2°C deviation obtained with a single-thermistor network [5]. Applications for NTC thermistors include temperature measurement, control, and compensation.

When current flows through a thermistor, there is a self-heating effect caused by the power dissipated in it. The thermistor temperature rises until the rate of heat loss from the thermistor to its surrounding environment equals the power dissipated. For this condition of thermal equilibrium, the temperature rise is directly proportional to the power dissipated in the thermistor. The constant of proportionality δ is the dissipation constant of the thermistor. By definition, δ is the ratio — at a specified ambient temperature, mounting condition, and environment — of the change in power dissipation in a thermistor to the resultant body temperature change. Factors that affect the dissipation constant are the thermistor surface area, the thermal conductivity and relative rate of motion of the medium surrounding the thermistor, the heat loss due to free convection in a still medium, the heat transfer between the thermistor and its mount through the thermistor lead wires, and heat loss due to radiation (significant for gases at low pressure). Because the thermal conductivities of fluids vary with temperature and free convection depends on the temperature difference between the thermistor and its ambient, δ is not a true constant. For gases in particular, the dissipation constant varies both with the thermistor body temperature and the amount of self-heating.

The thermal time constant τ is the 63.2% response to a step-function change in the thermistor temperature when the power dissipated in the thermistor is negligible. The thermal time constant only has meaning when there is a single exponential response. In such a case, an elapsed time of τ results in a 63.2% change between the initial and final steady-state temperatures, while an elapsed time of 5τ results in a 99.3% change. For a more complex structure, such as a thermistor encapsulated in a sensor housing, multiple exponentials can exist and one cannot predict that the 99% response will occur after an interval of five time constants. As with the dissipation constant, the thermal time constant is dependent on the rate of heat transfer between the thermistor and its environment. Consequently, all of the factors that increase the dissipation constant decrease the time constant.

The most common types of silicon PTC devices are the glass diode package having diameters of 1.8 mm to 2.5 mm and lengths of 3.8 mm to 7.5 mm, and the molded epoxy package with diameters of 3.6 mm to 6.0 mm and lengths of 10.4 mm to 15.0 mm. Such units have axial leads. Epoxy-coated chips and disks with radial leads also are available, with diameters of approximately 3 mm. Silicon PTC thermistors that comply with MIL-T-23648 have an operating temperature range of −55°C to 125°C. Commercial versions can be obtained with a range of −65°C to 150°C [6].

The most common configuration for switching-type PTC thermistors is the radial lead disk, with and without an insulating coating. Such units are available in diameters of 4 mm to 26 mm. The thickness dimension is in the range between 0.5 mm to 6.5 mm. They also are available as surface-mount devices, disks without leads, and in glass diode packages. Switching-type PTC disks have a storage temperature range of −25°C to 155°C and an operating range of 0°C to 55°C [1].

The emphasis of this text will be on NTC thermistors. Most thermistor applications use such devices. Two major categories of NTC thermistors exist. Bead-type thermistors have platinum alloy lead wires sintered into the body of the ceramic. Chip, disk, surface-mount, flake, and rod-type thermistors have metallized surface electrodes. The latter category includes glass diode packages in which dumet leads are compression-bonded to disks or chips.

Glass-coated beads include both adjacent and opposite lead configurations with diameters of 0.125 mm to 1.5 mm. Glass probes with diameters of 0.4 mm to 2.5 mm have lengths ranging from 1.5 mm to 6.35 mm. Probes with diameters of 1.5 mm to 2.5 mm have lengths of 3 mm to 12.7 mm, while larger probes with diameters of 2 mm to 2.5 mm have lengths of up to 50 mm. Glass rods typically are 6.3 mm long with diameters of 1.5 mm to 2.5 mm. A glass probe consists of a bare-bead-type thermistor sealed
at the tip of a solid glass rod and radial dummets. A glass rod, by comparison, has its bead sealed in the center of a solid glass rod and has axial dummets. The temperature range specified in MIL-T-23648 is −55°C to 200°C for glass-coated beads and −55°C to 275°C for glass probes and glass rods. Commercial versions of such glass-enclosed devices typically have a range of −80°C to 300°C. Some units are rated for intermittent operation at 600°C, while special cryogenic devices are rated for operation in the range of −196°C to 25°C.

Chip thermistors with radial leads are available with cross-sections of 0.25 mm × 0.25 mm to 13 mm × 13 mm and a thickness range of 0.175 mm to 1.5 mm. Disks having diameters of 1 mm to 25 mm are available in both radial and axial lead configurations, with a thickness range of 0.25 mm to 6.35 mm. Chips and disks also are available in glass diode packages with axial dummets. Surface-mount chips are available in sizes ranging from 2 mm to 3.2 mm long × 1.1 mm to 1.6 mm wide × 0.36 mm to 1.3 mm thick. Flake thermistors with both adjacent and opposite leads are available in a thickness range of 0.025 mm to 1.25 mm, with cross-sections of 0.5 mm × 0.5 mm to 3 mm × 3 mm. The temperature range specified for chips, disks, rods, and glass diode packages in MIL-T-23648 is −55°C to 125°C. Commercial chips and disks are available with an operating temperature range of −80°C to 155°C [1]. Rods are available for use over the range of −60°C to 150°C [7], and glass diode packages are available with an operating range of −60°C to 300°C [8].

Thermal Properties of NTC Thermistors

The energy dissipated as heat in a thermistor connected to an electric circuit causes the thermistor body temperature to rise above the ambient temperature of its environment. At any instant, the applicable heat transfer equation is:

\[
\frac{dH}{dt} = P = E_T I_T = \delta (T - T_a) + cm \frac{dT}{dt} \tag{32.26}
\]

where \( \frac{dH}{dt} = P = E_T I_T \) = Rate of thermal energy or heat supplied to the thermistor
\( \delta = \) Dissipation constant
\( T_a = \) Ambient temperature
\( \delta (T - T_a) = \) Rate of heat loss to the surrounding environment
\( c \) and \( m = \) Respectively, specific heat and mass of the thermistor
\( cm \frac{dT}{dt} = \) Rate of heat absorbed by the thermistor

The solution of Equation 32.26 when \( P \) is constant is:

\[
T = T_a + \frac{P}{\delta} \left[ 1 - \exp \left( -\frac{\delta}{cm} t \right) \right] \tag{32.27}
\]

The transient solution of Equation 32.27 is the basis for the current–time characteristic of a thermistor. When, \( t = cm/\delta \), then \( dT/dt \rightarrow 0 \), and the steady state solution of Equation 32.27 becomes:

\[
P = E_T I_T = \delta (T - T_a) \tag{32.28}
\]

where \( E_T \) and \( I_T \) are the steady-state thermistor voltage and current, respectively. Equation 32.28 is the basis for the voltage–current characteristic of a thermistor.

By reducing the thermistor power to a value that results in negligible self-heating, \( P \rightarrow 0 \), Equation 32.26 becomes:

\[
\frac{dT}{dt} = -\frac{\delta}{cm} (T - T_a) \tag{32.29}
\]
Equation 32.29 is a mathematical statement of Newton's law of cooling and has the solution:

\[ T = T_i + \left( T_a - T_i \right) \exp \left( -\frac{t}{\tau} \right) \]

where \( T_i \) = Initial thermistor body temperature
\( T_a \) = Ambient temperature
\( \tau = \frac{cm}{\delta} \) = Thermal time constant

Table 32.8 gives dissipation and time constant data for glass-coated beads, glass probes, and glass rods. Table 32.9 lists similar data for chip, disk, and rod-type thermistors with metallized surface contacts. Data for the dissipation and time constants are for the thermistor suspended by its leads at 25°C using the procedure specified in MIL-T-23648A. The temperature increment used for computing the dissipation constant results from self-heating the thermistors to 75°C from an ambient of 25°C. The time constant data result from allowing the thermistors to cool from 75°C to an ambient of 25°C. The water-plunge time constant data result from rapidly immersing the thermistors from room temperature air into still water. The transit time was negligible. The air temperature was approximately 25°C and the water temperature was about 5°C. The diameters specified for epoxy-coated interchangeable units are maximum diameters. To illustrate the effect of the environment on the thermal properties of these units, the

**Electrical Properties of NTC Thermistors**

Thermistor applications depend on three fundamental electrical characteristics. These are the voltage–current characteristic, the current–time characteristic, and the resistance–temperature characteristic.

**Voltage–Current Characteristics**

Figure 32.17 shows a typical voltage–current curve. At low currents, the power dissipated is small compared with the dissipation constant and the self-heating effect is negligible. Under these conditions, the resistance is constant, independent of the current, and the voltage is proportional to the current. Consequently, at low currents, the characteristic curve is tangent to a constant resistance line equal to the zero-power resistance of the thermistor. As the current increases, the effects of self-heating become more evident; the thermistor temperature rises, and its resistance begins to decrease. For each subsequent incremental increase in current, there is a corresponding decrease in resistance. Hence, the slope of the voltage–current characteristic decreases with increasing current. This continues until the current reaches a value at which the slope becomes zero. Beyond this point, at which the voltage exhibits its maximum value, the slope continues to decrease and the thermistor exhibits a negative resistance characteristic. The temperature, voltage, and current corresponding to the peak of the curve are:

\[
T_p = \frac{\beta - \sqrt{\beta^2 - 4\beta T_s}}{2}
\]  

(32.30)
where
\[ T_P = \text{Absolute temperature (in K) at which the peak occurs} \]
\[ T_a = \text{Absolute ambient temperature (in K)} \]
\[ R_P = \text{Thermistor resistance at } T_P \]

Applications based on the voltage–current characteristics involve changes in the operating point on a single curve or family of curves. Such changes result from changes in the environmental conditions or variations in circuit parameters. Figure 32.17 shows a graphical solution for obtaining the operating point. The curve represents a nonlinear relationship between the thermistor voltage and current. The Thevenin equivalent circuit with respect to the thermistor terminals provides the relationship given by Equation 32.33.

\[ E_T = E_{\text{THEV}} - I_T R_{\text{THEV}} \]  
(32.33)

where \( E_T \) and \( I_T \) are the thermistor voltage and current, respectively. The straight-line relationship of Equation 32.33 is the load line of the self-heated thermistor. Its intersection with the voltage–current characteristic is the operating point. Table 32.10 categorizes the more familiar applications into four groups distinguished by the form of thermistor excitation [1, 14].

Current–Time Characteristics
The voltage–current characteristics discussed above deals with a self-heated thermistor operated under steady-state conditions. This condition, for which a decrease in thermistor resistance results from a current sufficiently high to cause self-heating, does not occur instantaneously. A transient condition exists in a thermistor circuit from the time at which power is first applied (\( t = 0 \)) until the time equilibrium occurs (\( t \rightarrow \tau \)). The relationship between the thermistor current and the time required to reach thermal equilibrium is the current–time characteristic. Generally, the excitation is a step function in voltage through a Thevenin equivalent source. Figure 32.18 shows the current–time characteristics for several
thermistor disks and voltage sources. For any given characteristic, the source voltage, source resistance, and thermistor zero-power resistance determine the initial current. The source voltage, source resistance, and voltage–current characteristic determine the final equilibrium value. The curve between the initial and final values depends on the circuit design parameters, as well as the dissipation constant and heat capacity of the thermistor. The proper choice of thermistor and circuit design results in a transient time range of a few milliseconds to several minutes.

Applications based on the current–time characteristic are time delay, surge suppression, filament protection, overload protection, and sequential switching.

Resistance–Temperature Characteristics
The term zero-power resistance applies to thermistors operated with negligible self-heating. This characteristic describes the relationship between the zero-power resistance of a thermistor and its ambient temperature. Over small temperature spans, the approximately linear relationship between the logarithm of resistance and inverse absolute temperature is given by:

$$\ln R_T = A + \frac{\beta}{T}$$

where

- $T =$ Absolute temperature (K)
- $\beta =$ Material constant of the thermistor

![Graph showing current-time characteristics](image)

**FIGURE 32.18** Current–time characteristics of Thermometrics, Inc. epoxy-coated chip thermistors. Curves A and C are for a DC95F402 having a zero-power resistance at 25°C of 4 kΩ. Curve B is for a DC9F802 having a zero-power resistance at 25°C of 8 kΩ. The excitation is a step function in voltage through a Thevenin equivalent source. The source voltage and resistance values for curve A are 24 V and 1 kΩ, respectively. For curves B and C, the source voltage is 48 V and source resistance is 2 kΩ.
If one lets $R_T = R_{T_0}$ at a reference temperature $T = T_0$ and solves for $R_T$, one obtains:

$$R_T = R_{T_0} \exp \left[ \frac{\beta (T_0 - T)}{T T_0} \right]$$

(32.35)

The temperature coefficient of resistance $\alpha$ is defined as:

$$\alpha = \frac{1}{R_T} \frac{dR_T}{dT}$$

(32.36)

Solving Equation 32.34 for $\alpha$ yields:

$$\alpha = \frac{\beta}{T^2}$$

(32.37)

In Equation 32.34, the deviation from linearity results in temperature errors of 0.01°C, 0.1°C, and 0.3°C for temperature spans of 10°C, 30°C, and 50°C, respectively, within the range of 0°C to 50°C. Using a polynomial for $\ln R_T$ vs. $1/T$ reduces the error considerably. The degree of the polynomial required depends on the temperature range and material system used. The use of a third-degree polynomial is adequate for most applications. Hence, more accurate expressions for the resistance–temperature characteristic are:

$$\ln R_T = A_0 + \frac{A_1}{T} + \frac{A_2}{T^2} + \frac{A_3}{T^3}$$

(32.38a)

$$\ln R_T = A_0 + \frac{A_1}{T} + \frac{A_2}{T^2} + \frac{A_3}{T^3}$$

(32.38b)

$$\frac{1}{T} = \alpha_0 + \alpha_1 \ln R_T + \alpha_2 \left( \ln R_T \right)^2 + \alpha_3 \left( \ln R_T \right)^3$$

(32.39)

Steinhart and Hart proposed the use of Equation 32.39 for the oceanographic range of −2°C to 30°C [11]. Their analysis showed that no significant loss in accuracy occurred by eliminating the square term $a_2 (\ln R_T)^2$. Consequently, they proposed the use of Equation 32.40.

$$\frac{1}{T} = b_0 + b_1 \ln R_T + b_2 \left( \ln R_T \right)^3$$

(32.40)

Mangum reported that the use of Equation 32.40 resulted in interpolation errors of approximately 0.001°C over the range of 0°C to 70°C [12].

The technical staff at Thermometrics, Inc. evaluated Equation 32.38 over the range of −80°C to 260°C using 17 different thermistor materials. The glass probes investigated encompassed a span of specific resistance values of 2 Ω cm to 300 kΩ cm and a resistance range at 25°C of 10 Ω to 2 MΩ. The results were presented at the Sixth International Symposium on Temperature and show that the interpolation errors do not exceed the total measurement uncertainties. For temperature spans of 100°C within the range of −80°C to 260°C, 150°C within the range of −60°C to 260°C, and 150°C to 200°C within the

© 1999 by CRC Press LLC
range of 0°C to 260°C, the interpolation errors are 0.005°C to 0.01°C [13]. Lowering the temperature span to 50°C within the range of 0°C to 260°C reduces the interpolation error to 0.001°C to 0.003°C.

Sapoff and Siwek [14] evaluated the loss in accuracy introduced by eliminating the quadratic term in Equation 32.38. For this condition, Equation 32.38 reduces to Equation 32.41.

\[
\ln R_t = C_0 + \frac{C_1}{T} + \frac{C_3}{T^3}
\]  

(32.41)

The interpolation errors introduced by Equations 32.40 and 32.41 depend on the material system, temperature range (nonlinearity increases at low temperatures), and the temperature span considered. Table 32.11 summarizes the errors associated with the use of Equation 32.41 for various temperature spans and ranges.

Equations 32.38 through 32.41 can be rewritten as:

\[
R_t = \exp \left( A_0 + \frac{A_1}{T} + \frac{A_2}{T^2} + \frac{A_3}{T^3} \right)
\]  

(32.42)

\[
T = \left[ a_0 + a_1 \ln R_t + a_2 \left( \ln R_t \right)^2 + a_3 \left( \ln R_t \right)^3 \right]^{-\frac{1}{3}}
\]  

(32.43)

\[
T = \left[ b_0 + b_1 \ln R_t + b_2 \left( \ln R_t \right)^3 \right]^{-\frac{1}{3}}
\]  

(32.44)

\[
R_t = \exp \left( C_0 + \frac{C_1}{T} + \frac{C_3}{T^3} \right)
\]  

(32.45)

The solutions for Equations 32.38, 32.39, 32.42, and 32.43 require four calibration points and the use of simultaneous equations. Similarly, the solutions for Equations 32.40, 32.41, 32.44, and 32.45 require three calibration points. The use of a polynomial regression analysis involving additional calibration points can minimize the effects of calibration uncertainties.

Applications that depend on the resistance–temperature characteristic are temperature measurement, control, and compensation. There also are applications for which the thermistor temperature depends on some other physical phenomenon. For example, an hypsometer is an instrument in which the temperature of a boiling liquid provides an indication of the liquid vapor pressure. Another example involves the use of thermistor-type cardiac catheters for thermodilution analysis. A saline or dextrose

solution of known volume and temperature is injected into the bloodstream through one of the catheter lumens. The mixing of the solution with the blood dilutes the solution and decreases the temperature of the blood as it flows downstream past a thermistor located at the surface of another lumen in the catheter. The cardiac output computed from the temperature–time response data measured by the thermistor provides an indication of the heart pump efficiency.

**Linearization and Signal Conditioning Techniques**

The measured resistance and computed constants for Equations 32.43 and 32.44 can be used with a computer to determine temperature without the need for a linear network. This is useful for obtaining high accuracy over relatively wide temperature ranges. Most applications based on the resistance–temperature characteristics of thermistors, however, use some form of linearization or signal conditioning. The use of a constant current source and a linear resistance network provides a voltage output that is linear with temperature. By using the proper combination of current and resistance level, a digital voltmeter connected across the network provides a direct display of temperature. The use of a constant voltage source results in a linear conductance network with a current that is linear with temperature.

**Linear Conductance Networks**

Voltage dividers, ohmmeter circuits and Wheatstone bridge circuits are linear conductance networks. Consider the voltage divider circuit shown in Figure 32.19. Using the fixed resistor for the output eliminates the effect of the load resistance. For the purpose of analysis, the resistor denoted by \( R \) is the parallel combination of the load and fixed divider resistors. Another advantage is that the output voltage increases with temperature with this arrangement. The ratio of output voltage to input voltage is given by:

\[
\frac{e_0}{e_s} = \frac{R}{R + R_T} = \frac{1}{1 + R_T/R}
\]  

(32.46)

where:
- \( e_0 \) = Output voltage
- \( e_s \) = Source voltage
- \( R \) = Parallel combination of the load and fixed resistors
- \( R_T \) = Thermistor resistance at a specified temperature \( T \)
If one normalizes the thermistor resistance with respect to its value at a specified reference temperature \( T_0 \), then:

\[
r_r = \frac{R_T}{R_{T0}}
\]  

where \( R_{T0} \) = Thermistor resistance at \( T_0 \)

\( r_r = \) Resistance ratio

Thermistor manufacturers typically supply resistance ratio–temperature characteristics in their catalogs. Substituting Equation 32.47 in Equation 32.46 yields:

\[
e_r = \frac{1}{1 + r_r \frac{R_{T0}}{R}}
\]  

(32.48)

If the circuit constant \( \sigma = \frac{R_{T0}}{R} \), then Equation 32.48 becomes:

\[
F(T) = \frac{e_r}{e_0} = \frac{1}{1 + r_r \sigma}
\]  

(32.49)

The output for the voltage divider of Figure 32.19a is the S-shaped curve shown in Figure 32.19b. The value of the circuit constant \( \sigma \) determines the temperature range for which good linearity exists between \( e_0 \) and \( T \). References [3, 4] include families of S-shaped curves over the range \( 0.01 \leq \sigma \leq 20.0 \) for the three basic material systems of MIL-T-23648. A good criterion for achieving optimum linearity is to equate the slopes of the function \( F(T) \) at the end-points of the specified temperature range \( T_L \leq \sigma \leq T_H \). Specifying that \( \frac{dF(T_L)}{dT} = \frac{dF(T_H)}{dT} \) results in the following:

\[
\sigma = -\frac{X - Y}{Yr_{T_L} - Xr_{T_H}}
\]  

(32.50)

where \( X \) and \( Y \) are determined by the end-point conditions and the equation constants for \( \ln R_r \) vs. \( T \). When Equation 32.41 is used, \( X \) and \( Y \) are given by:

\[
X = T_H \sqrt{r_{T_L} \left( C_1 + 3 \frac{C_3}{T_H^2} \right)}
\]  

(32.51)

\[
Y = T_L \sqrt{r_{T_H} \left( C_1 + 3 \frac{C_3}{T_L^2} \right)}
\]  

(32.52)

When Equation 32.38 is used, \( X \) and \( Y \) are given by:

\[
X = T_H \sqrt{r_{T_L} \left( A_1 + 2 \frac{A_2}{T_L} + 3 \frac{A_3}{T_L^2} \right)}
\]  

(32.53)
By allowing $e$ and $R$ to be the Thevenin equivalent voltage and resistance with respect to the thermistor terminals, respectively, the voltage divider analysis applies to any more complex circuit such as a Wheatstone bridge [3, 4].

Thermistor self-heating constraints typically result in nonstandard voltage sources for thermometer circuit designs. The modified divider circuits of Figure 32.20 provide equivalent circuits with standard voltage sources. Only a portion of the available output voltage appears across the output detector in Figure 32.20a. Ohmmeter-type thermometers use such circuits. The circuit of Figure 32.20a provides the full available output voltage. However, the conversion results in a bias voltage in series with the output. Bridge circuit-type thermometers use the circuit of Figure 32.20b. The conversion equations applicable to Figure 32.20a are:

\[
K = \frac{R}{R_1 + R_2} = \frac{E_1}{E_2} = \frac{R_1}{R_2}
\]  

(32.55)

FIGURE 32.20  Equivalent thermistor voltage divider circuits for converting a network with a nonstandard voltage source to a network that uses a standard voltage source. Only a portion of the output is available in (a). Ohmmeter-type thermometers use such circuits. The conversion circuit of (b) provides the full available output voltage in a series with a bias voltage. (b) is used with bridge circuit-type thermometers.

\[
Y = T_L \sqrt{\frac{R}{T_H \left( \frac{A_1}{A_1} + 2 \frac{A_2}{A_1} + 3 \frac{A_3}{A_1} \right)}}
\]  

(32.54)
The conversion equations applicable to Figure 32.20 are:

\[ R = R_3 + R_4 = R_5 + \frac{R_2 R_3}{R_2 + R_3} \]  \hspace{2cm} (32.56)

\[ E_2 = \text{Desired source voltage} \] \hspace{2cm} (32.57)

\[ R_2 = \frac{R_1}{K} \] \hspace{2cm} (32.58)

\[ R_1 = \frac{R_2 R_3}{R_2 - R_4} \] \hspace{2cm} (32.59)

\[ \left( \frac{R_3}{R_3 + R_4} \right) F(T) \] \hspace{2cm} (32.60)

The conversion equations applicable to Figure 32.20b are:

\[ K = \frac{R_2}{R_2 + R_3} = \frac{E_1}{E_2} = \frac{R}{R_1} \] \hspace{2cm} (32.61)

\[ R = \frac{R_1 R_2}{R_1 + R_2} \] \hspace{2cm} (32.62)

\[ E_2 = \text{Desired source voltage} \] \hspace{2cm} (32.63)

\[ R_5 = \frac{R}{K} \] \hspace{2cm} (32.64)

\[ R_2 = \frac{R R_1}{R_2 - R} \] \hspace{2cm} (32.65)

\[ \epsilon_n = (E_2 - E_1) + \epsilon_{n_1} \] \hspace{2cm} (32.66)

Reference [15] includes design examples that use these conversion equations.

**Temperature Controllers.**

Thermistor temperature controllers frequently use voltage divider and bridge circuits. The use of a thermistor in such a circuit results in much higher sensitivity than that obtainable with a thermocouple or RTD. The most sensitive standard thermocouples exhibit output voltage slopes of 50 to 55 μV °C⁻¹ in the range of 0°C to 300°C. Thermistor voltage dividers typically exhibit output slopes of about 8 to 10 mV °C⁻¹ per volt applied to the divider. Since the input to a thermistor voltage divider typically is in the range of 1 to 5 V, a thermistor provides about 200 to 1000 times the sensitivity of a thermocouple. The temperature coefficient of resistance of a thermistor is about 10 times that of an RTD. However, the temperature span about the control point of a thermistor controller is small compared with that available with a thermocouple or RTD.

© 1999 by CRC Press LLC
Reference [1] includes some typical low-cost thermistor temperature controllers. Thermistor temperature controllers are available from Hart Scientific, Inc. that provide control stabilities of better than 0.001°C [16].

**Linear Resistance Networks**

A common technique for designing a thermometer circuit is to apply a constant-current source to a linear resistance network. This results in a voltage across the network that is linear with temperature. Temperature compensation for resistance changes that occur in coil windings, instruments, relays, motors, and generators also use such networks. For example, a copper coil has a positive temperature coefficient of resistance of approximately 0.39% °C⁻¹. The thermistor network has a negative temperature coefficient. The compensator is designed to provide a slope that is equal in magnitude, but opposite in sign to that of the copper coil. Hence, the Ω vs. °C slope of the compensator is equal to the Ω/°C change of the coil. This results in a current through the coil that is independent of temperature. Additional applications include compensation of drift in silicon strain gages, infrared detectors, and circuits that contain both passive and active components.

For the basic linear resistance network of Figure 32.21a:

\[ R_{12} = R_C = \frac{R R_T}{R + R_T} = R \left( 1 - \frac{1}{1 + R_T / R} \right) \]  

(32.67)

Normalizing with respect to \( R \) and substituting \( r_T = R_T / R \) and \( R_T / R = \sigma \) in Equation 32.67 yields:

\[ R_n = \frac{R_C}{R} = 1 - \frac{1}{1 + r_T \sigma} = 1 - F(T) \]  

(32.68)

Consequently, the techniques used for optimizing the linearity of voltage dividers also apply to linear resistance networks. The use of the series resistor \( R_1 \) in Figure 32.21b, translates the curve to a higher resistance level and does not affect the Ω/°C output.
Frequently, the design of a compensator that provides the desired $\omega/{^\circ}C$ output results in a thermistor that has a nonstandard $R_{T0}$ value. The conversion circuit of Figure 32.21 permits the use of a standard $R_{T0}$ value. The conversion equations are as follows:

\begin{align*}
K_i &= \frac{R'_{T_{10}}}{R_{T_{10}}} \\
R_e &= R_i - R\left(K_i - 1\right) \\
R_A &= RK_i\left(K_i - 1\right) \\
R_B &= RK_i
\end{align*}

where $R_{T_{10}}$ is the nonstandard value and $R'_{T_{10}}$ is the standard value. A requirement is that both thermistors have the same resistance ratio–temperature characteristic. Setting $R_i = R(K_i - 1)$ in Figure 32.21 results in $R_e = 0$ for Figure 32.21c. Consequently, the conversion of Figure 32.21 to that of Figure 32.21 requires the use of the minimum insertion resistance $R_i = R(K_i - 1)$.

The network provides good linearity for small temperature spans of 10°C to 30°C. However, the error increases rapidly from about 0.15°C for a 30°C span to 0.7°C for a 50°C span (0°C to 50°C). The use of the two-thermistor network shown in Figure 32.22 results in a maximum linearity error of 0.22°C over the range of 0°C to 100°C, while the three-thermistor network shown reduces the error to 0.04°C for the same 0°C to 100°C range [5]. The networks shown in Figure 32.22 are linear voltage dividers. Placing the resistor $R_i$ across the output terminals 3–4 converts these networks to linear resistance networks. Many manufacturers sell an interchangeable, three-wire, dual thermistor that is suitable for use in the two-thermistor circuit of Figure 32.2.

Interchangeable thermistors and the linearization techniques described above have been available for many years. In addition, the stability of NTC thermistors is better than that of thermocouples and frequently better than or equal to that of commercial RTDs [17]. However, the nonlinear resistance–temperature characteristics of thermistors continue to limit their use in industrial temperature measurement and control applications. The availability of low-cost microprocessors has eliminated this limitation. Such devices can use the equation constants of Equations 32.38 or 32.39 to compute and display temperature directly. They also can be used to compute lookup tables to provide interpolation uncertainties in the
range of 0.001°C to 0.01°C. There are instruments described in the literature that utilize such microprocessor chips [18, 19]. Thermometrics, Inc. sells a commercial instrument that reads the equation constants from a chip in the connector of each probe supplied for use with the instrument [1]. The use of thermistors for industrial applications will continue to increase as the cost of microprocessor chips continues to fall.

32.4 Thermocouple Thermometers

R. P. Reed

The Simplest Thermocouple

Despite an increasing variety of temperature sensors, the self-generating thermocouple remains the most generally used sensor for thermometry because of its versatility, simplicity, and ease of use. Any pair of
electrically conducting and thermoelectrically dissimilar materials coupled at an interface is a \textit{thermocouple} [1]. The legs are \textit{thermoelements}. The \textit{Seebeck effect} produces a voltage in all such thermoelements where they are not at a uniform temperature. Any electric interface between dissimilar electric conductors is a \textit{real thermoelectric junction}. A free end of a thermoelement is a \textit{terminus}, not a junction. Couplings between \textit{identical} thermoelements are \textit{splices} or \textit{joins}, not junctions.

It is the thermoelements that determine thermocouple sensitivity and calibration; but, it is the temperatures of the end-points of thermoelements (i.e., junction temperatures) that determine the \textit{net emf} observed in thermometry. The Seebeck effect, which converts temperature to voltage, is used for thermoelectric thermometry but is also a primary low-frequency noise source in all low-level electronic circuits [2].

### Simple Thermocouple Thermometry

In the simplest applications, thermocouple thermometry now is as easy to use as is a multimeter to measure resistance. In fact, many present-day digital multimeters (in addition to voltage, current, and resistance) do provide a thermocouple temperature probe, and temperature measurement is just another button-selectable function. These thermocouple thermometers consist of an indicator that digitally displays the temperature of the tip of a plug-in thermocouple probe (Figure 32.24). The simpler of such versatile multimeters can be purchased for less than U.S.$60 [3]. Interchangeable thermocouple probes of different standard thermocouple material types and specialized sensing tips of widely varying designs are adapted to measurement from surface temperatures to internal temperatures in foodstuffs [4].

With some probes, temperatures up to 1370°C can be indicated merely by (1) ensuring that the selected thermocouple types of the indicator and probe correspond, (2) pressing a power-on button, and (3) applying the probe tip at the point where temperature is to be measured. Promptly, and without calibration, the present temperature of the probe tip is digitally displayed selectively in °C or °F, usually to a resolution of 0.1°C or 1°F. Some specifications claim “accuracy” of 0.3% (4°C at 1370°C) of reading. Some even offer certified \textit{calibration traceability} to NIST or other national standards laboratory.

Modern digital electronics has created the illusion that very accurate thermocouple thermometry is no different than other routine electrical measurements. It has encouraged the perception that arbitrarily fine accuracy can be always be accomplished by calibration and guaranteed by certification. The remarkable simplification of instruments that is now commonplace and an abundance of misleading tutorials obscure the real need for a sound understanding of principles of thermocouple circuits for anything other than inconsequential thermometry.

Manufacturers can shelter users from many problems inherent in thermocouple application. Unfortunately, there are many pitfalls from which the manufacturer cannot isolate the user by design or construction. In less simple applications, it is necessary for the user to avoid problems by carefully learning

\begin{figure}
\centering
\includegraphics[width=\textwidth]{figure32.24.png}
\caption{The simple modern digital thermocouple thermometer. Modern digital electronics has made casual thermometry very easy, but has obscured the continuing need to have an authentic understanding of thermoelectric principles for accurate thermometry with more complicated circuits and more important measurements.}
\end{figure}
and applying the true principles of thermoelectric circuits and thermocouple thermometry. Even the simplest indicators and probes can easily be misused and produce unrecognized substantial error.

Thermometry errors of only a few °C or even much less in energy, process, manufacturing, and research fields annually cost many millions of dollars in lost yield, fuel cost, performance bonuses, etc. Consequence of error can also be incurred as incorrect interpretation of data, failure of objective, equipment damage, personal injury, or even loss of life.

Unusual thermocouple circuits, installations, and special applications often produce inconspicuous error or else peculiar results that are very puzzling if an authentic model of thermoelectric circuits is not understood. This chapter section presents the factual principles of thermoelectric circuits that equip the user to easily apply thermocouples for reliable and critical thermometry, even in unusual circumstances with justified confidence. These principles are very simple, yet they justify study even by experienced thermocouple users as thermoelectric circuits are very often misrepresented or misunderstood in subtle ways that, although unrecognized, degrade measurement. The aim of the chapter section is to allow thermometry with all practical simplicity while avoiding possibly costly measurement errors.

**Thermoelectric Effects**

The three thermoelectric phenomena are the Seebeck, Peltier, and Thomson effects [1, 2, 5-7]. Of these, only the Seebeck effect converts thermal energy to electric energy and results in the thermocouple voltage used in thermometry. The current-dependent Peltier and Thomson effects are insignificant in practical thermometry. Neither produces a voltage, contrary to common misconceptions. The Peltier and Thomson effects only transport heat by electric current and redistribute it around a circuit. Thermocouple thermometry is properly conducted by open-circuit measurement. The Seebeck emf occurs even without current where Peltier and Thomson effects necessarily vanish. Related thermo-magneto-electric effects are significant only in the presence of large magnetic fields and infrequently degrade applied thermoelectric thermometry [2, 5, 6].

**The Seebeck Effect**

The Seebeck effect is the occurrence of a net source emf, the absolute Seebeck emf, between pairs of points in any individual electrically conducting material due to a difference of temperature between them [1, 2, 5, 7, 8]. The Seebeck emf occurs without dissimilar materials. It is not a junction phenomenon, nor is it related to Volta’s contact potential.

**Absolute Seebeck Properties**

The absolute Seebeck coefficient expresses the measurement sensitivity (volts per unit of temperature) of the Seebeck effect. It is defined over any thermoelectrically homogeneous region of a slender individual conducting material by:

$$\sigma(T) = \lim_{\Delta T \to 0} \Delta E/\Delta T = \frac{dE}{dT}, \text{ or}$$

$$dE = \sigma(T) dT$$  \hspace{0.5cm} (32.74)

The Seebeck coefficient is a transport property of all electrically conducting materials. Equation 32.74 will be acknowledged later as the functional law that governs thermoelectric emf. From Equation 32.74,

$$\Delta E = \int_{T_1}^{T_2} \sigma(T) dT = E(T_2) - E(T_1)$$  \hspace{0.5cm} (32.75)

where $\Delta E$ is the increment of emf between a pair of points, separated by any distance, between which the temperature difference is $\Delta T = (T_2 - T_1)$. 
From Equation 32.75, the net Seebeck effect for a particular material depends only on the temperatures at the two points and not on the values of temperature gradients between the two points. The Seebeck coefficient is a nonlinear function of temperature. It is not a constant. For accurate thermometry, the Seebeck coefficient must remain dependent on temperature alone. $\sigma(T)$ cannot vary along a thermoelement, nor can it vary significantly during the time interval of use. Although vulnerable to such environmental effects, for accurate thermometry it must not depend during measurement on such environmental variables as strain, pressure, or magnetic field.

The coefficient, $\sigma_{M}(T)$, is an absolute Seebeck coefficient for an individual material $M$ \cite{1,2,7,8}. A corresponding source voltage within a single material is an absolute Seebeck emf, $E_{M}(T)$. The absolute Seebeck emf does physically exist but it is not simply observable. The absolute Seebeck coefficient can be determined indirectly by measuring the Thomson coefficient, $\tau$, of the individual material and applying a Kelvin relationship,

$$\sigma = \int_{0}^{T_{ah}} \left( \tau/T_{ah} \right) dT \quad (32.76)$$

to deduce the thermodynamically related Seebeck coefficient \cite{1,2,5,7,8}.

Relative Seebeck Properties

The difference between the Seebeck emfs of two thermoelements, of materials A and B, of a thermocouple with their shared junction at temperature, $T_{m}$, and both their termini at a physical reference temperature, $T_{r}$, is their relative Seebeck emf, $E_{AB}(T)$, expressed as:

$$E_{AB}(T_{m},T_{r}) = E_{A}(T_{m},T_{r}) - E_{B}(T_{m},T_{r}) \quad (32.77)$$

The corresponding relative Seebeck coefficient for the pair is:

$$\sigma_{AB}(T_{m},T_{r}) = \sigma_{A}(T_{m},T_{r}) - \sigma_{B}(T_{m},T_{r}) \quad (32.78)$$

It is this relative Seebeck coefficient that has been called by the anachronistic and inept term “thermopower” \cite{1}. It is these relative voltage or coefficient values that are directly observable and usually used in thermometry. These relative properties, defined for convenience in the series circuits of thermometry, have no general meaning for electrically paralleled thermoelements \cite{2}. These are the relative values that are presented in the familiar tables of thermocouple emf vs. measuring junction temperature, $T_{m}$, referred to as a designated reference temperature $T_{0} = T_{r}$ \cite{1,4,9-12}. For convenience, $T_{0}$ is usually taken as 0°C, but the value is arbitrary.

Realistic Thermocouple Circuits

The thermocouple is often represented as only a pair of dissimilar thermoelements joined by two junctions in a closed circuit. One junction, at temperature $T_{m}$, is the measuring junction; the other, at temperature $T_{r}$, is the reference junction. The net Seebeck emf is proportional to the temperature difference between the two junctions and to a relative coefficient for the paired materials.

The Seebeck phenomenon has wrongly been characterized as the occurrence of current in the closed loop. The true nature of the Seebeck phenomenon is the occurrence of a source emf that, for accurate thermometry, must be measured in open-circuit mode that suppresses current. In practical thermometry, no realistic thermocouple circuit has only two dissimilar materials. Some have many and several of these can be expected to contribute some Seebeck emf. The most common thermometry circuits have two separate reference junctions, not one. Valid, but uncommon, circuits can simultaneously have more than one reference temperature \cite{1}. 

© 1999 by CRC Press LLC
Reference Temperature

The physical reference temperature, \( T_r \), can be different from the designated reference temperature, \( T_0 \), of the characterizing relation. If \( T_r \) is not identical to \( T_0 \), then, to use standard scaling functions, the observed thermocouple emf must be corrected for the temperature difference by adding an emf equivalent to \( E_{AB}(T_r) - E_{AB}(T_0) \) to the observed thermocouple emf [1, 7, 9-12]. This is often accomplished by separately monitoring \( T_r \) and applying a correction, either numerically or electrically, using a fixed \( E_{AB}(T) \) relation that only approximates that of the actual thermocouple and the standardized characteristic over a limited range in the vicinity of \( T_0 \) and \( T_r \). The error due to the slight discrepancy between the approximation and the actual \( E_{AB}(T) \) is small if the two temperatures are similar.

Special thermocouple extension leads are used in most applied thermometry. Many industrial principal thermocouples are inflexibly metal sheathed [1, 4, 10-12]. Others have bare thermoelements separated by bead insulators. Often, these kinds of assemblies are housed in protective wells, have measuring junctions of complex construction, or are distant from the monitoring instrument. Short “pigtails” and extension leads can be of larger wire size, lower resistance, greater flexibility, and very different rugged cable construction than the principal thermocouple (Figure 32.24). All thermoelements must be very well electrically isolated except at measuring and reference junctions. Most modern thermometry is conducted with variants of two basic circuits.

Circuit with Single Reference Junction.

Figure 32.25 shows a thermometry circuit now used mostly in calibration laboratories. This form is convenient when a fixed point temperature reference such as an ice point bath or water triple point cell is used to impose the known physical reference temperature, \( T_r \) [1, 7, 9-12]. The circuit of the thermocouple indicator between \( a \) and \( f \) inconspicuously includes many incidental materials and complex circuitry within the instrument. It is necessary that \( T_i = T_e = T_r \). Unless instrument temperatures are constant throughout measurement, any nonsothermal portion of the circuit within the instrument can contribute Seebeck emf as noise. This emf can be correctly offset only if it is constant.

Often, in circuits like Figure 32.25, the measuring junction, \( b \) of the principal thermocouple, and reference junction, \( e \), are provided by separately acquired thermocouples \( a-b-c \) and \( d-e-f \). The two might have significantly different calibrations although they are nominally of the same thermocouple material type. With \( T_m \) at 40°C and \( T_0 \) at 0°C the reference, thermocouple \( d-e-f \) contributes about half the Seebeck emf.

This commonplace circuit has at least four distinct thermoelement materials — A, A’, B, and B’ — each of which must be homogeneous. Also, they can be joined, as between c and d, by an intermediate uncalibrated linking material, C (unless \( T_c = T_d \), material C contributes unwanted Seebeck emf). If B
and B' are not identical in Seebeck characteristics, then c (and/or d) are real junctions. If so, it is also necessary that $T_c = T_d$. The termini a and f, when connected to a monitor, also become real junctions. They must be controlled so that both stay at the same temperature.

In Figure 32.25, for thermometry the physical reference temperature is intended to be $T_e$. However, monitoring instruments that internally compensate for reference junction temperature presume (incorrectly for this circuit) that $T_r = T_a = T_f$. Therefore, the single-reference circuit of Figure 32.25 cannot be used directly with thermocouple instruments that automatically apply reference junction temperature compensation.

Circuits with Dual Reference Junctions.

In the simple "black box" thermocouple thermometer (Figure 32.24), as well as in most applied thermoelectric thermometry, the most common circuit is that of Figure 32.26. This circuit is now the most commonly used in modern thermocouple thermometry. The thermocouple c-d-e with thermoelements joined at the measuring junction, d, is the principal thermocouple. This circuit might have only the principal thermocouple with a plug and jack at the indicator input. More often, as in Figure 32.24, the relatively inflexible principal thermocouple probe also has flexible extension leads, pair C-D, which can reside unseen within the indicator. Dashed pair A'-B' schematically represents internal reference junction temperature compensation.

Circuits like Figure 32.26 have two separate reference junctions that must be held at the same known temperature. Net Seebeck terminal voltage is measured between b and f. When thermocouple leads C and D are connected to the monitor, the input terminals, b-f, might be intended to be reference junctions. If so, their reference temperature is accurately monitored and emf reference correction corresponding to the difference between $T_e$ and $T_d$ is applied. Accurate thermocouple measurements cannot be made with ordinary voltmeters in which the temperatures of b and f are not deliberately controlled to be equal and known.

Extension Leads

Paired thermoelements C and D are thermoelectric extension leads. Extension leads are of three kinds: (1) neutral, (2) matching, and (3) compensating. All types are readily available; some are proprietary. Which of the junctions in Figure 32.26 must be reference junctions varies with the type of extension. Depending on the extension type, materials A, B, C, and D might, intentionally, all be of very different materials.

Neutral Extension Leads.

In the simplest application of Figure 32.26, legs C and D are thermoelectrically homogeneous and are carefully matched to have the same Seebeck coefficient ($\sigma_c = \sigma_d$). Such pairs are neutral extension leads. Provided that $T_c = T_e$ and $T_b = T_f$, they contribute no net Seebeck emf, so the like pair function effectively serve only as "passive" leads. Therefore, the leads could be made of any electrically conducting material. Such extension leads should be made of solid unplated copper, for which the Seebeck coefficient is small and uniform.
Neutral extension leads require that junctions \( c \) and \( e \) be the reference junctions at temperature \( T_r = T_s \). Thermocouple monitors that provide reference junction temperature compensation at input terminals \( b \) and \( f \) cannot be used with neutral extension leads.

The reference temperature can be controlled on both junctions by a fixed point physical temperature reference such as an ice bath external to the voltage monitor [1, 9-12]. Ice baths, very carefully made and maintained, can routinely approximate 0°C to within 0.1°C to 0.2°C [9, 11]. Carelessly applied and maintained, they can deviate from the “icepoint temperature” by up to 4°C [10]. Peltier thermoelectric refrigeration is also used. More often, in thermometry, that reference temperature is not physically imposed. Instead, the actual temperature of the reference junctions is accurately measured and electrical compensation is applied (schematically by \( A' \)-\( B' \)) for the difference between \( T_r \) and \( T_0 \). The particular value of the temperature at \( b \) and \( f \) does not matter if \( T_b = T_f \) is compensated.

Complementary Extension Leads.

Two kinds of complementary extension leads are allowed to contribute to the circuit Seebeck emf: matched and compensating extensions. The legs \( C \) and \( D \) are thermoelectric extension leads that are usually uncalibrated, and possibly are of broader or even unknown tolerance. It is expected that \( T_s \) and \( T_i \) are similar so that the uncalibrated contribution is small and the error is negligible. For very accurate thermometry, this assumption might not be justified.

Complementary extension leads can be used directly with thermocouple indicators that internally compensate the reference junction temperature for the difference between the physical reference junction temperature, \( T_r \), and the designated reference temperature, \( T_0 \). For both matched and compensating complementary extensions, the reference temperature is \( T_r = T_i \) over the isothermal reference zone around the terminals \( b \) and \( f \).

Matching Extension Leads.

Matching leads have \( \sigma_c = \sigma_A \) and also \( \sigma_D = \sigma_B \). It is essential that \( T_b = T_i \), but it is not essential (although it is desirable) that \( T_c = T_e \). Near room temperature, thermoelements are intended to have \( \sigma_{CD} \) as a pair, be nearly the same as \( \sigma_{AB} \) for the temperature span near \( T_r \). Error due to slightly mismatched and unproven calibration of the extension is minimized if \( T_c \equiv T_e \). Matched extensions are used with base metal thermocouples, not with refractory or precious metal thermocouples.

Compensating Extension Leads.

The third variation of the circuit in Figure 32.26 is often used for economy and convenience with expensive precious and refractory metal principal thermocouples that are intended for use at very high temperatures and in special environments [1, 7, 9-12]. Usually, only a portion of the principal thermocouple need be exposed to the adverse environment. Extension leads \( C \) and \( D \) need only survive a more benign environment. Therefore, they can be made of a less expensive or more conveniently handled material, use lower temperature insulation, be more flexible and of lower resistance, add bulky shielding and mechanical protection, and extend a great distance to a recording facility.

Compensating leads have \( \sigma_{CD} \) of the extension \( C-D \), only as a pair, match \( \sigma_{AB} \) of the \( A-B \) pair. It is not necessary that material \( A \) be like \( C \), nor that \( C \) and \( D \) be alike. A practical circuit can have four very dissimilar materials. However, to allow this, it is essential that \( T_c = T_e \). Therefore, this circuit with compensating leads is more vulnerable to error from improperly matched temperatures of incidental junctions than with matching extension leads. The reference junction temperature is \( T_i = T_o = T_p \), and only this temperature must be independently known. Reference junction compensation is the same as for the matching leads.

Modular Signal Conditioning Components

The myriad of diverse and capable thermocouple indicators and recorders now commercially available, ranging from simple and very inexpensive to sophisticated and versatile yet reasonably priced, makes it unnecessary for most applied thermometry to assemble special signal conditioning circuits. Some, seeking economy of hardware, have built custom systems. Too often, these have not achieved accurate measurement
and have proved to be very costly because the critical distinctions between thermoelectric circuits and ordinary electric circuits were not appreciated. For special situations where thermocouples are incorporated into special measurement or operational components or systems, several manufacturers now offer modular and integrated circuit components that simplify special application and do protect the unaware from some pitfalls [13].

Thermocouple Signal Conditioning on a Chip.
As thermocouple signals are low level, it is sometimes desired to amplify them for improved resolution, recording, or control. It might be desirable to incorporate thermocouple sensing as a functional component in other instrumentation packages. There are now several miniature and inexpensive integrated circuit modules for thermocouples that provide reference junction compensation, linearization, isolation, open input indication, amplification, and set point control. Properly applied, these make the integration of thermocouple sensing into other devices, such as computer data acquisition boards, very simple [13].

When a user applies modular components such as these, it is particularly important to understand and to apply the authentic thermoelectric circuit model and principles introduced in the section “The Functional Model of Thermoelectric Circuits.” Some precautions normally provided in commercial thermocouple monitors must be provided by the user.

Reference Temperature Sensors.
Thermocouples are self-generating. For casual approximate temperature and differential temperature measurement, they require neither excitation nor reference temperature. For accurate thermometry, unless a known reference temperature is physically imposed, an accurate measurement of the reference junction temperature by independent means is necessary. This sensing is usually by powered resistance temperature detectors, thermistors, transistors, or integrated circuit sensors [1, 4].

Reference Temperature Compensators.
Proper reference compensation requires (1) the establishment of an isothermal temperature zone that includes the terminals of the thermocouples, (2) sensing of the temperature of this zone, and (3) application of a complementary physical or numerical voltage to the thermocouple terminal voltage before scaling the total voltage to temperature.

An analog method includes the resistive zone temperature sensor in a bridge that nonlinearly modulates a supplied voltage according to an approximated nonlinear curve of the \( E(T) \) characteristic of the thermocouple. This method is adapted to compensation of only a single thermocouple type. An alternate method numerically converts the sensed reference temperature to the appropriate compensating voltage value. The numerical approach allows applying a separate compensating voltage to each individual thermocouple and for different standard types. In principle, for accuracy, a numerical compensating voltage could be programmed by the user to conform to the specific calibration of the individual thermocouple, whether or not of standardized type.

Reference temperature compensators are internal to the more advanced thermocouple monitors. In advanced units, eight to ten thermocouple inputs are grouped on a separately removable isothermal terminal assembly so they can be removed for reference sensor calibration or for replacement. Like thermocouples, reference sensors occasionally drift, causing significant temperature error. For most thermocouple types, a 1° error in temperature reference produces a similar error in the measured temperature. A variety of external battery- or line-powered, single- or multichannel reference junction compensating units are also commercially available [4, 14].

**Grounding, Shielding, and Noise**
The technically well-founded principles of noise control for electric circuits apply also to thermoelectric circuits [15, 16]. There are, however, some additional considerations that are necessary for thermocouple circuits. Some noise control problems stem from the nature of thermoelectricity; others from commercial thermocouple design practices.
Noise Problems Peculiar to Thermocouples

Temperature control of all deliberate and incidental junctions and components, and the distributed nature of Seebeck source emf, cannot be ignored with impunity in thermocouple application. The unavoidable requirements of such control are best visualized using methods such as given later in “The Functional Model of Thermoelectric Circuits.” Incidental circuit components such as balancing or swamping resistors, feedthrus, splices, and terminal strips, not intended to contribute Seebeck emf, must deliberately be maintained isothermal. Shields, unavoidably nonisothermal, made electrically common with the thermocouple must be explicitly recognized as latent sources of random dc noise which contributes Seebeck emf if not properly connected.

Electromagnetic (EM) Noise

In thermocouple probes of mineral-insulated metal-sheathed (MIMS) construction, ceramic-bead-insulated thermocouples, and in some paired insulated thermocouple wires, the paired thermoelements are not twisted and are well separated. Lengthy and larger diameter thermocouple probes present a significant circuit loop area to couple magnetic noise fields. Even if probes are entirely metal-sheathed, the standardized sheaths are very thin and of low magnetic permeability. They are scarcely effective for electromagnetic (EM) shielding. These features prevent the use of some classic techniques for the rejection of EM noise [15, 16]. To reduce troublesome EM noise, the principal thermocouple probe should be of the smallest practical diameter, and of minimum length. In instances where the EM source is localized and identified, the orientation of the probe relative to the source can be arranged to minimize EM coupling. For rejection of EM noise, extension leads should always be of twisted-pair construction, with a pitch small enough to reject high-frequency noise [15].

Electrostatic (ES) Noise

Electrostatic noise is more easily reduced. Shields of low resistance, though thin, can be effective if properly connected [15, 16]. Plated copper braid is commonly used and is effective for noise of moderate frequency. Continuous shields, such as the MIMS sheaths and aluminized mylar film, are effective for low-frequency ES noise and are more effective than braid shields for very-high-frequency noise. Electrostatic shields must be continuous (without gaps and holes as in braid) for maximum effectiveness. Optimum benefits from shielding require use with thermocouple monitors that provide three-wire input and multiplexers that, individually for each thermocouple, switch both the signal pair and their separate shield lead.

Grounding

Shielding for ES noise and pair twisting for EM noise are important for reduction of high-frequency noise. A secondary overall shield, isolated from inner shields and separately grounded, can improve the rejection of EM noise. Appropriate circuit grounding is also particularly important for both high-frequency EM and ES control, but it is even more significant for low-frequency and dc noise, which are often more consequential in thermocouple measurements. Appropriate grounding is complicated where intimate thermal contact of the measuring junction with an earth-grounded conducting test subject is needed for rapid transient thermometry or for accuracy in the presence of static temperature gradients. Figure 32.27 illustrates appropriate grounding for several of many possible situations. Low-level thermocouple circuits should be grounded only at a single electric reference point. Because the measuring junction is not a localized site of source emf, the point of grounding must be carefully considered. Grounding should never be at any point of the thermocouple circuit other than measuring or reference junctions. Electric contact, and particularly shunting or shorting, on a thermoelement at any point between measuring and reference junctions usually introduces spurious Seebeck emf from incidental unrecognized thermoelements.

Allowable grounding might be dictated by the internal design of monitors and data loggers. Each instrument design addresses noise control in a distinctive way. Simple and inexpensive line-powered thermocouple thermometers might have only single-ended inputs with the negative lead internally
connected to the power ground. This forces the sensor grounding to also refer to power ground. A grounded-junction arrangement might also be required for fast transient thermometry. In use, initially isolated thermocouples can short to the protective sheath or test subject. Although this does change the grounding configuration, resulting errors due to other effects usually are then predominant.

**Balanced Thermocouple Circuits**

The more sophisticated multichannel data acquisition systems specialized to thermocouple thermometry usually have high-resistance balanced inputs for high common-mode signal rejection. Some differential input amplifiers require significant input resistance for stability. Most have an internal chassis that provides a common signal reference guard surface that is well-isolated from power ground. In a few designs, the guard is electrically driven to a particular reference point. Because many variations are used, it is prudent to study and follow the specific grounding instructions recommended in the user’s manual for the instrument. Most accommodate alternative grounding arrangements.

---

© 1999 by CRC Press LLC
In sheathed thermocouple probes of standard MIMS dimensions, the thermoelements are of the same cross-section, parallel and well spaced, and located within the cylindrical sheath symmetrically [10]. Noise tends to be coupled equally to the paired thermoelements in common mode. However, lengthy or fine gage thermocouples have legs of high resistance compared to copper circuits. The ratio between the resistances of the dissimilar legs can be up to 25:1. Noise introduced in common mode adversely tends to convert to normal mode.

In addition, unlike most voltage sources, the Seebeck emf is not localized to the measuring junction (a material interface). The emf can arise anywhere along the thermoelements. In transient thermometry, it first occurs adjacent to, and then spreads away from the measuring junction. In the more commonplace static thermometry, the site of source emf is usually distant from the measuring junction.

Most specialized thermocouple recorders provide reference temperature compensation. They do not allow convenient user access to the circuit beyond the reference junctions. This restricts the noise control methods available to the user. For externally referenced thermocouples, some effective simple circuit modifications are possible. Figure 32.28 shows the addition of three resistors that, used with monitors of balanced input, improve noise rejection. Isothermal balancing resistor, \( R_c = |R_a - R_b| \), is added in series with the thermoelement of lower resistance. Making the resistance of the two circuit branches equal reduces the undesired conversion of noise from common mode to normal mode. The matched pair of shunting resistors, \( R_s \), presents a significant definite minimum source resistance to the amplifier input for stability and symmetrically couples the signals and sheath to the common reference point. The resistors must be large enough, \( R_s \geq 1000 \ (R_a + R_b) \), to avoid significant shunting resistive attenuation of the thermocouple source Seebeck emf. With great care to maintain these resistors strictly isothermal, the balancing and shunt resistors could be placed just at the input terminals external to the instrument-provided reference junction temperature compensation.

**Filtering**

For low-frequency thermometry, to complement the user-provided passive rejection of EM and ES noise by proper grounding and shielding, internal filtering provided by data acquisition monitor manufacturers can effectively reject high-frequency noise. Filtering before recording is preferred. This control can be performed by conventional filters; but for quasi-static thermocouple measurements, other very effective techniques such as "double-slope integration" are provided in some designs. These techniques effectively average the signal over several measured samples. The noise reduction and stability under real-life conditions is remarkable. Routine resolution and stability to 0.1 \( \mu \text{V} \) variation over a period of days is achieved by many modern thermocouple data loggers. However, this noise rejection method restricts the sampling speed so that samples can be limited to intervals no shorter than 10 ms to 20 ms that are unsuited to very fast transient thermometry.
Thermal Coupling

Accurate thermometry obviously requires that the temperature of thermocouple measuring junctions closely agree with the temperatures to be measured. In static measurements at thermal equilibrium, this is often easy to accomplish. In fast transient measurements, it can be very difficult.

Static Thermometry

Thermocouple thermometry of steady-state or slowly varying temperatures requires close thermal coupling of the measuring junctions to the point of measurement. This agreement of temperatures naturally occurs by equilibration if the point of measurement can be chosen to be well within a region that stays at uniform temperature during measurement. Even in such nearly static thermometry, the thermoelements should be as small as practical to reduce any conduction of heat along the thermocouple that could affect the temperature being measured.

In typical situations, however, the vicinity of the measuring point is not isothermal and, even at steady state, static temperature gradients can cause the measuring junction to be at a significantly different temperature from the subject [18]. This source of error is more severe for surface, liquid, and gas measurements than for internal solid measurements, and is aggravated for the measurement of subjects of low thermal mass. Efficient thermal coupling of the thermocouple to the subject, as in Figure 32.27, is essential.

Noise or safety might require electrical isolation of the thermocouple. Commonplace electrical insulating materials are poor thermal conductors. There are now special greases, coatings, and thin sheet materials available designed to provide high electrical isolation, yet good thermal contact [17]. Where needed, they can improve accuracy by efficient thermal coupling.

Transient Thermometry

Monitoring very rapid variations of temperature is most effectively accomplished by thermocouples because of the low sensing mass and small size of measuring junction that they allow. Fast thermal response requires the use of special thermoelement configurations in the vicinity of the measuring junction, special circuitry, special thermocouple monitoring instruments, and characterizing methods [16, 18]. Some suppliers offer very thin (10 μm thick) foil and fine wire thermocouples that are especially well adapted to such measurement [19, 20].

A thermocouple alone has no characteristic response time. The Seebeck effect occurs at electronic speed. The thermocouple source emf always promptly corresponds to the temperatures of all junctions in the circuit. However, the transient temperature response of a thermocouple installation is very much slower, and is primarily governed by the thermal interaction of the thermocouple components adjacent to the junctions and the adjacent mass of the test subject [18, 22, 23]. That slow conductive heat transfer is retarded many-fold by even a thin film of air, vacuum, or an insulting solid layer. In fast transient thermometry, the electrical parameters of the thermocouple and associated circuitry and dynamic response of the recording system can further degrade response time.

Intimate thermal coupling by special materials required for static measurement in a thermal gradient is even more critical to transient than to static thermometry [17]. Even the special coupling materials slow response. They should be as thin as feasible. For very fast thermometry, such coupling might not be tolerable. It may be necessary to place the bare measuring junction in direct electric contact with the subject (Figure 32.27).

Intrinsic Thermocouples

Where the subject of thermometry is an electric conductor, it is possible to electrically fuse the two thermoelements separately to the test subject. This is an “intrinsic” thermocouple junction arrangement. Fine wires or thin foils spot-welded to the subject allow the fastest possible electrothermal response and reduce the influence of the thermocouple on the temperature being measured.

Observe two special precautions in the use of intrinsic junctions. First, the two thermoelements should be fused to the subject side-by-side, close together (not one over the other.) With intrinsic junctions, the
bridging segment of the subject becomes a part of the series thermoelectric circuit. (There are two intrinsic junctions coupled by the intermediate subject material.) This produces the fastest response; but in very fast transients, the temperatures of the two junctions can very briefly be slightly different and thus introduce a momentary error, as the unknown Seebeck coefficient of the bridging subject material is different from that of one or both of the principal thermoelements [21].

Second, for transient thermometry, the fine thermoelements leading to the intrinsic junctions should be as short and fine as feasible to reduce their thermal loading; however, this results in a relatively high electric lead resistance. A strain-relieved transition from the fine filaments to more substantial low-resistance compensating lead wires should be made near the measuring junction to enhance electric response. The electrical effect of capacitive coupling of the circuit on electric transient response must also be minimized.

Numerical Correction.
All feasible physical techniques to achieve fast transient temperature response when applied might not be sufficient for a very fast measurement. An inadequate transient response can be further enhanced by numerical analysis [21]. Two additional steps must be taken.

First, an authentic experimental or correctly modeled transient response characterization of the overall thermal-electrical thermometry system must be made. The usual simplistic first-order representations of in situ thermocouple response might be inadequate [21–23].

Second, this authentic characterization must be applied by mathematical deconvolution to better estimate the true temperature history of data indicated by a system that had inadequate physical transient response [16, 19]. Critical and reliable improvements of effective response time by factors of four or more are often possible. If uncorrected, indicated transient peak temperatures can be in error by a much greater percentage than the error that results from static thermocouple calibration error. No general uncertainty can be assigned to a transient measurement without such response characterization.

Thermocouple Materials

Thermocouple Standardization
Many materials are in regular use as thermocouples for thermometry. Some pairs are standardized; some are not. The distinction is a matter of formal consensus group approval by balanced standards committees of experienced users, producers, and standards laboratory staff [10, 24]. The most extensive application data is available for standardized thermocouples. In the U.S., eight materials presently are letter-designated (Types B, E, J, K, N, R, S, and T) [9–12, 24]. Some properties of these are summarized in Table 32.12. The standardized $E(T)$ characteristics of these are now defined exactly by polynomial functions of high degree rather than by tabulated values [1, 9, 10]. Thermoelements should be used as selectively paired for thermocouples by the producer, as randomly paired thermoelements of the same type from the same or different manufacturers are not assured to conform to the standard pair values or tolerances [1, 9–12].

The properties of a few other popular pairs, such as precious metal and tungsten refractory alloys, have also been committee-proposed, but letter designations and color codes have not been formally assigned [10]. Infrequently, other popular materials are considered for standardization. Limited Seebeck and application information is available for a multitude of nonstandard materials [25, 26].

Low Temperature Thermometry
Most thermometry is at elevated temperatures. Thermocouple measurement of temperatures below the ice point requires special consideration. Cryogenic thermometry has been very loosely defined as measurement below 280 K (7°C) [1]. More restrictively, the defined cryogenic range has been limited to below 90 K (~183°C, the boiling point temperature of liquid oxygen at 1 atm) [1]. The former range broadly overlaps the measure of atmospheric temperatures (down to ~50°C) below the ice point that, along with higher ambient temperatures, often are measured by a single thermocouple system. The latter definition favors characterizing as cryogenic only the extremely low-temperature regime over which thermometry involves distinctive severe problems and different techniques.
The Seebeck coefficient of all conductors is insignificant at 0 K and common materials progressively decrease in thermoelectric sensitivity below the ice point. A few natural superconductor metal elements experience an abrupt drop in Seebeck coefficient to zero at a characteristic superconducting threshold that is below 10 K for most unalloyed metal superconductors [27]. Special alloys have recently been developed to raise the superconducting threshold to about 120 K — well above the formal cryogenic

- Overall jacket color.
- Chromel and Alumel are trademarks of Hoskins Mfg. Co.
- Initial tolerances are for material as manufactured and used within recommended temperature range, Table 32.15, protected in a benign environment.
- Recommended temperature range is a guideline for service in compatible environments and for short durations.

The Seebeck coefficient of all conductors is insignificant at 0 K and common materials progressively decrease in thermoelectric sensitivity below the ice point. A few natural superconductor metal elements experience an abrupt drop in Seebeck coefficient to zero at a characteristic superconducting threshold that is below 10 K for most unalloyed metal superconductors [27]. Special alloys have recently been developed to raise the superconducting threshold to about 120 K — well above the formal cryogenic
range. Superconducting transitions complicate thermoelectric thermometry at the lowest cryogenic temperatures [7, 8].

Standard Seebeck characteristics are defined for Types E, J, K, N, and T down to –270°C. The characteristics for Types R and S extend only down to –50°C, and Type B is not characterized below 0°C. The standard polynomials that define the Seebeck properties of letter-designated thermocouples and the production tolerances for commercial materials are different for temperatures below and above the ice point. Materials manufactured for thermometry at elevated temperatures might conform less well to the standard cryogenic characteristics than alloys of the same type especially furnished for such use [1]. This quality issue should be discussed with the thermocouple supplier. Special alloys are available for cryogenic thermometry.

For the lower cryogenic range, of the letter-designated thermocouple materials, Type E is preferred for use down to –233°C (40 K) because of its higher relative Seebeck coefficient [1]. The less-sensitive Type K and Type T are also used in this range. Below 40 K, special alloy combinations, such as Type KP vs. Au/0.07 Fe, are recommended. Special thermoelectric relations apply to these materials in the cryogenic range [1].

As Peltier heating at junctions and Thomson heating along thermoelements are current-dependent thermoelectric effects, neither is a significant problem if thermometry is properly conducted by open-circuit measurement. There is no significant thermocouple self-heating as with resistance thermometers. Some thermoelement alloys experience grain growth and incur serious inhomogeneity under prolonged exposure to deep cryogenic temperatures. More sensitively at cryogenic temperatures than at elevated temperatures, the Seebeck coefficient of most thermocouple alloys is very strongly dependent on magnetic field. Strong magnetic fields are often involved in cryogenic experiments, so thermo-magneto-electric effects become significant in studies of superconductivity [2, 27].

**Sensitivity**
The need for large thermocouple output has been drastically reduced by the enhanced sensitivity, stability, and noise suppression of modern solid-state digital thermocouple indicators. These instruments can routinely indicate temperature to 0.1°C resolution and stability for all letter-designated types. The standard pairs differ significantly in their sensitivity (Table 32.12). The sensitivity of the Type E thermocouple is 10 times that of the Type B thermocouple at 1000°C. Because the Type B thermocouple has extremely small sensitivity around room temperature, it is intended for use only with the measuring junction above 870°C. The most sensitive standardized thermocouple, Type E, has a maximum Seebeck coefficient of 81 μV °C⁻¹ and, referenced to 0°C, has a maximum Seebeck emf of 76 mV. While initial tolerances for both normal- and special-grade material have been standardized, the difference between commercial and premium grades is small and, in use, special-grade materials can degrade to exceed the initial tolerances of the normal-grade material.

**Letter Designations**
The U.S. ANSI standard letter designations and color codes for eight particular thermocouple types (B, E, J, K, N, R, S, and T) were first established by the ISA in Standard MC-96.1 [28]. The same conventions are followed by Standards of the ASTM and ANSI [10, 24]. A first suffix to the type letter designator, P or N, as in types KP or KN, designates the positive or negative thermoelement of a thermocouple pair. A final “X” suffix designates an extension wire material, as in KPX for a positive type K extension thermoelement. For non-standardized material pairs, producers and vendors often apply their own unofficial letter designations, color codes, and trade names. These commercial identifiers of individual manufacturers have no universal meaning.

**Color Codes**
Intended to ease identification, the standards of many nations have assigned color codes to the different letter-designated thermocouples and to thermoelements and extensions. As the individual thermoelements determine both polarity and sensitivity, it is very important to properly identify each leg. Color codes now used in the U.S. are shown in Table 32.12.
U.S.-standardized color codes have remained uniform for several decades; thus color code confusion of material types in the U.S. is mostly due to user carelessness. The present globally discordant color codes can cause costly misinterpretation in multinational use, particularly outside the U.S. where neighboring countries and trading partners have unlike or multiple color codes. Clearly, a single universal international color code accepted by all nations would be beneficial. Such an international color code is embodied in standard IEC 584 that is being considered by several nations [28].

Unlike the standardized Seebeck characteristics that are fairly uniform worldwide, the uncoordinated color codes of different national standards are very inconsistent. The unfortunate Babel of national color codes that existed in 1998 is displayed in Table 32.13 [1, 4].

Unfortunately, and uniquely, in present U.S. thermocouple standards, the negative thermoelement is always red, contrary to customary U.S. electrical and instrument practices. This is also contrary to the historic national thermocouple color codes of China, Germany, and Japan, in which red designates the positive thermoelement. In English standards, the negative leg of all types is blue.

Std. ANSI IEC BS NMI NFC42 DIN JIS
No. MC096.1 584-3 1843 42-323 43714 1620

From References [1, 4, 9, 10].
In France, the positive thermoelement is always coded yellow. However, a yellow positive leg in the U.S. standard designates Type KP material. The wire leads of some U.S. electric blasting caps use yellow insulated wire with a parallel red tracer that has been confused with Type KX thermocouple extension wire. In England, yellow denotes Type JP material. The white positive and black negative of the present U.S. ANSI color code for Type J are transposed in international standard IEC 584.

Despite the clear desirability for a uniform color code, there remains a huge quantity of material of different color codes in stock and in use worldwide. For any nation that switches to any new color standard, there would be, immediately and over an unavoidable lengthy transition period following acceptance, the new color-coded thermocouple material intermixed with the multitude of inconsistent legacy color codes. The immediate possibility for confusion of material type would greatly increase rather than decrease. Also, even the present color codes can become indistinct on long-installed material, colors can fade, and/or colors may have been incorrectly applied in manufacture.

**Identifying Thermoelements**

The color codes apply directly to extension lead wires and effectively to the principal thermocouple wire. Many principal thermoelements and thermocouples are not color coded. A user might not correctly recall the color code. The prudent user will, before use, confirm material type identification independent of the color code. **Definite** type identification must be by a combination of methods. Any single identification method can be indefinite, and no method is adaptable to all materials or circumstances.

**Visual Identification.**

TP thermoelements are of copper and thus are distinguished by their distinctive reddish color. JP thermoelements are iron and have a distinctive matte gray cast. Other base metal alloys and platinum and its alloys, if bare, all have a very similar bright silvery appearance unless, if bared from compressed mineral insulation, fabrication has effected a roughened gray matte surface appearance.

**Magnetic Identification.**

Type JP (iron) is strongly magnetic. Type KN (Alumel) is slightly magnetic. All other standard thermoelement materials are nonmagnetic. JP and KN thermoelements can be distinguished from the others by testing the attraction to them of a small magnet.

**Resistive Identification.**

Resistivities of thermoelements are given in Table 32.12. Although assembled thermocouples have a measuring junction that cannot generally be removed for testing, a bare junction can be directly accessible or it can be electrically accessible at a probe tip for resistance measurement of each leg if the junction is of the type made common at the measuring junction to a conductive sheath. Thermocouple assemblies or cable usually have paired thermoelements of the same length and cross-section. The resistance of each leg distinguishes the material if the wire size and length are known. In these instances, with both ends of the cable at the same temperature, the resistance of each thermoelement can be directly measured. The ratio between positive and negative leg resistances can aid type confirmation. For assembled thermocouples with inaccessible measuring junctions, only the loop resistance can be measured and compared with calculated loop resistances.

**Thermoelectric Identification.**

Less conveniently, a pair can be identified by the output for a known temperature of measuring junction and reference junction. **Complementary extension cables** can be thermally identified by temporarily forming a junction between a pair at one end. Identification can be definite using a less precise procedure than necessary for formal calibration. For identification, both reference and measuring junction temperatures must be independently known or measured. The approximate temperature of the reference junction can be determined by momentarily shorting the input directly at the indicator input terminals of an instrument that provides reference compensation. Because the thermocouple material might not correspond to the compensation applied, the temperature must be determined separately.

The temperature applied to the measuring junction for identification must be at least 200°C because uncertainty of the thermocouple calibration and of the imposed temperature makes unreliable the emf.
distinction of thermocouple pairs, such as $E$ from $J$, and $K$ from $N$ or $T$ using either ice or boiling water baths. Very similar Types $R$ and $S$ can be reliably distinguished only at much higher temperatures or by formal calibration.

**The Functional Model of Thermoelectric Circuits**

For simplicity, the relation between junction temperatures required for accurate measurement was merely asserted in the section on “Practical Thermocouple Circuits,” without any physical explanation. Some subtle problems of realistic thermoelectric circuits are difficult to visualize without an explicit circuit model. A simple, practical, and general-purpose model of thermoelectric circuits now explains why those temperature structures are appropriate. More significantly, it makes clear the consequences of deviation from these temperatures. It illuminates the common problems of calibration and inhomogeneity. It explains why the commonplace misconception that the Seebeck emf is localized to junctions can lead to serious error in general thermocouple circuits.

Real thermocouple circuits involve several materials and incidental real junctions, often many more than in Figures 32.24 or 32.25. The incidental uncontrolled materials of feedthrus, terminals, splices, etc. might not be recognized as source elements, yet they can, unnoticed, contribute significant unwanted Seebeck emf to the measurement. Therefore, for practical thermocouple thermometry, it is essential to understand and use a descriptive circuit model that is simple to apply and that forces the attention to locations of potential error so that problems can be avoided.

One such authentic model, the *Functional Model of Thermoelectric Circuits* [1, 2, 5, 7, 29–31], combines (1) a basic thermoelectric circuit element, (2) a single fundamental law that describes the sensitivity of that element, (3) a set of practical corollaries from that law that illuminate its practical implications, and (4) a graphic tool for circuit visualization to simplify analysis. This very simple but nontraditional model is crafted for practical thermometry and is worth studying.

**The Basic Thermoelectric Circuit Element**

Any thermoelectrically homogeneous nonisothermal segment of arbitrary length of material M within any thermoelement is a **Seebeck cell**. Each such segment across which a net temperature difference exists (Figure 32.29) is a **non-ideal voltage source** with internal resistance $R(T)$. The Seebeck **source emf** must be observed in an “open-circuit” (null current) mode for the most accurate thermometry. Any $iR$ voltage

---

**FIGURE 32.29** The Seebeck emf cell. Every homogeneous, nonisothermal, electrically conducting material is a source of Seebeck emf. The basic cell, a nonideal voltage source with internal resistance, contributes a Seebeck emf that depends only on the material M and the temperatures at the segment end-points 1 and 2.
drop due to current allowed by a low input resistance of the voltage monitor reduces the Seebeck source emf to a lower terminal Seebeck voltage. For thermometry, that voltage difference causes a temperature error unless corrected.

In static thermometry, as in calibration and in typical process measurement, the measuring junction and a substantial length of the adjacent thermoelements are immersed in a stationary and somewhat isothermal zone so that most of the Seebeck emf occurs well apart from the measuring junction in thermoelements where they cross remote temperature transition regions. In transient thermometry, the zone of principal temperature difference initially is adjacent to the measuring junction so that the emf arises across a region of spreading extent adjacent to, but not in, the measuring junction (a material interface).

The Law of Seebeck emf

Equation 32.74, \( dE = \sigma(T) dT \), is the functional law that governs the emf of the Seebeck cell and, thus, the net voltage of the most complex thermoelectric circuits. It is the Law of Seebeck emf. Every thermoelectric aspect of circuit behavior follows from only this simple relation. Physical details of the process that leads to the Seebeck effect are very complex \[5, 6\]. Nevertheless, this one simple law is entirely consistent with all physical theory and is experimentally confirmed. If this simple relationship does apply to the basic Seebeck cell then accurate thermometry is possible. If it does not, then accurate and reliable thermoelectric thermometry is not possible.

The source emf of an individual cell of material M, from Equation 32.75, is:

\[
\Delta E_M(T) = E_M(T) - E_M(T_i)
\]  

(32.79)

and, for thermally paired segments of materials A and B that happen at any instant to share a pair of end-point temperatures, regardless of their residence or proximity in a circuit,

\[
\Delta E_{AB}(T) = E_{AB}(T) - E_{AB}(T_i)
\]

(32.80)

They need not be directly joined at a junction (nor, indeed, be electrically joined). The values of \( E_{AB}(T) \) are obtained directly from the standard thermocouple polynomial defining equations, simpler representations of those equations, tables, or graphs \[1, 9–12\]. Absolute Seebeck properties for many materials are also available, but are less commonly reported \[1, 5, 7, 8\]. As is evident from this model, absolute properties could always be used in thermoelectric analysis. They must be used in some realistic circumstances where the conventional relative properties are meaningless or where the relative properties are not known.

Either the absolute Seebeck coefficient, the temperature increment across the segment, or both of them, can be either positive or negative. Therefore, the polarity of a cell within a circuit depends both on the material and, unlike the electrochemical emf cell, on the momentary sense of temperature difference across the segment. Polarity, and even function, changes with temperature distribution.

Corollaries from the Seebeck Law

From the single Law of Seebeck emf (Equation 32.74), five particularly instructive practical corollaries that aid thermoelectric circuit analysis have been recognized. These are the corollaries of: (1) functional roles, (2) functional determinacy, (3) temperature determinacy, (4) emf determinacy, and (5) Seebeck emf \[1, 2, 7, 29–31\]. These are stated in Table 32.14, abbreviated from \[29\]. These revealing corollaries relate more directly to practical thermometry than do the three familiar thermocouple “laws” \[32\] that actually are only oblique alternative corollaries to the sole physical law (Equation 32.74).

The T/X Visualization Sketch

The practical significance of the fundamental law and its corollaries for realistic thermoelectric circuits is revealed by a simple graphic sketch (Figure 32.30). The T/X sketch is used for visualization and numerical analysis only. It is not drawn to scale. It is not used for graphic solution. It illuminates essential
The facts that are not obvious from a conventional electrical schematic or $E(T)$ plot. The $T/X$ sketch shows the temperatures of all real junctions in the sequence in which they occur around the circuit. Real junctions are indicated by closed circles. Junctions are joined by thermoelements. The sketch is not drawn to scale, so slopes do not represent temperature gradients.

The $T/X$ sketch reveals that segments that span a temperature interval always occur in pairs — but significantly only in series circuits. It is this fact that allows the convenient use of relative Seebeck properties. This conventional simplification does not apply to circuits with paralleled branches [2]. The $T/X$ sketch, applied to the thermocouple circuit of Figure 32.26, depicts the significant circuit elements (the junctions and thermoelements) in a way that focuses on their unavoidable thermoelectric functions (Corollary 1). Figure 32.30 shows a circuit temperature distribution with junction temperatures $T_b$ that were shown (intentionally improperly different) to illustrate a principle and the benefit of the sketch.

### Temperatures of Incidental Junctions.

The reference junction temperatures must independently be accurately known for measurement. The unknown temperature of the measuring junction is to be deduced from the Seebeck voltage. The specific temperatures of all incidental real junctions of a circuit are rarely known accurately in practice. For use in the $T/X$ sketch, the actual values need not be accurately known. Nevertheless, if the relative values of all incidental junctions are not properly controlled, as described in the section “Practical Thermocouple Circuits,” and if some essential junction temperatures are not known well enough to draw the sketch, then accurate thermometry cannot be ensured! The revealing $T/X$ sketch requires no more information than is essential for the physical measurement.

In the estimate of measurement consequences and to visualize how junction temperatures must be controlled in circuits of many materials, it is sufficient to assume, for qualitative analysis, plausible relative
temperature levels and their consequences. The sketch is most often used for visualizing consequences by inspection [1, 2, 29–31]. Nevertheless, it also can aid in quantitative analysis of error for plausible temperature distributions.

Virtual Junctions and Thermoelements.
On the $T/X$ sketch, isotherms through real junctions intersect some thermoelements. It is useful for analysis to view these intercepts (e.g., $c'$ and $e'$), each marked by a tic, as virtual junctions. For inspection and analysis, they conveniently delineate the arbitrary temperature end-points of segments. Also, on the diagram, virtual thermoelements, $b$-$c$ and $f$-$g$ are indicated by dashed lines. These segments represent the imaginary thermoelectric source of complementary emf that must be supplied to extend the physical reference temperature, $T_r$, to the designated reference temperature value, $T_0$. The virtual thermoelements represent the reference junction compensation.

The $T/X$ sketch aids in assigning segment bounding temperatures and thus a polarity and an emf to each thermoelement in the circuit. The circuit is traversed on the sketch from one instrument terminal, conveniently the negative, to the other terminal. Then, if the absolute Seebeck coefficient of a thermoelement is positive, the emf contribution of the segment adds emf if the temperature increases in proceeding across the segment from the negative toward the positive instrument terminal, etc. For inspection and analysis, it is efficient to consider segments as thermally paired over a temperature zone bounded by isotherms.

Examples.
On the $T/X$ sketch, consider the absolute Seebeck emfs supplied by the four thermoelements of Figure 32.26. As connected in this series circuit, proceeding from negative to positive terminals, the net Seebeck emf of the physical circuit between terminals $b$ and $f$ is:

\[ E_{\text{net}} = E_c + E_A + E_B + E_D \]  

(32.81)

where

© 1999 by CRC Press LLC
Recall that these individual Seebeck emfs do physically exist in the thermoelements whether or not they are connected by junctions as a circuit. It is the temperature dependence of both the magnitude and the momentary polarity of emf that distinguishes thermoelectric from ordinary electric circuit analysis (Corollary 5).

Note that emf from thermoelement \( A \) can be rewritten as:

\[
E_A = E_A \frac{V_A}{T_A} - E_A \frac{V_A}{T_A}
\]  

(32.82)

This arbitrarily breaks thermoelement \( A \) into two segments joined at virtual junction \( e' \). Thermoelement \( D \) can be segmented as well. Now, across the shaded temperature zone between \( T_c \) and \( T_e \), there are improperly thermally paired segments \( c-e' \) and \( c'-e \). The net emf from these thermally paired segments is:

\[
E_{\text{net}} = E_A \frac{V_A}{T_A} - E_D \frac{V_D}{T_D}
\]  

(32.84)

From Equation 32.75, recognize that this is the relative Seebeck emf for the unintended \( A-D \) pair over that arbitrary temperature zone even though they are not directly joined in the circuit. That improper pairing of segments clearly is avoided only if \( T_c = T_e \), whatever the temperature. In the instance that Figure 32.26 represents a principal thermocouple \( A-B \) with matching extension leads \( C-D \), materials \( A \) and \( C \) are alike and \( B \) and \( D \) are alike. If the legs of extension leads \( C-D \) each exactly match the corresponding legs of thermocouple \( A-B \), then

\[
E_{\text{CD}} = E_{\text{AB}} \frac{V_A}{T_A}
\]  

(32.85)

and (for matching extension leads only) the accidental pairing is benign.

Otherwise, with compensating extension leads \((\sigma_A = \sigma_C \text{ and } \sigma_B = \sigma_D)\), error occurs even if \( \sigma_{cd} \) closely matches \( \sigma_{ab} \) as a pair but not individually. In the instance of neutral extension leads where \( C \) and \( D \) are alike, the net emf from the pair is null over the zone from \( T_b \) to \( T_c \). In this instance, the physical reference junction is recognized as necessarily \( T_c = T_e = T_r \), rather than \( T_c = T_e = T_f \).

If \( T_c \) and \( T_e \) were interchanged, the error would be of different magnitude, not merely of opposite sign, simply because of the temperature distribution (Corollary 2). The unknown temperature of only one junction can be determined; the others, including incidental junctions, must be defined by value or, indirectly, as being isothermal (Corollary 4).

Note that such relative contributions (the null net contribution from two opposed like segments or the inappropriate thermal mispairing between \( B \) and \( D \)) are immediately evident simply by inspection of the informal \( T/X \) sketch without tedious algebra. These critical facts of thermoelectric circuits are not evident from the usual electrical schematic or from \( E(T) \) plots.

Most real circuits include several incidental uncalibrated materials such as connectors, terminals, splices, feedthrus, short pigtails, or extension leads that each have their own (usually indefinite) Seebeck
properties. In some circuits, some thermoelements might accidentally be paralleled. It is important to include them in the sketch to recognize the unnoticed potential error that could be contributed by such circuit elements if they are not held isothermal. Also, multiple extension circuit elements might be improperly connected with crossed polarity. The specific voltage or temperature consequence of these situations is easily calculated for any plausible temperature distribution. The $T/X$ plot was designed specifically to aid in circuit visualization to avoid these very common practical problems and to easily assess their possible impact.

Inhomogeneity

The Nature of Inhomogeneity

A slender thermoelement is inhomogeneous if $\sigma_m(T)$ varies along its length. The environment during application can introduce irregular inhomogeneity in one or both thermoelements of a pair. The effect is as if one or more additional dissimilar materials had been added to the circuit.

The Significance of Inhomogeneity

Adequate thermoelectric homogeneity is the most critical assumption of thermocouple application. It usually is presumed; rarely is it confirmed. Inhomogeneity is a real but phantom problem. Inhomogeneity often remains undetected even while producing substantial error. It rarely is discovered by even the most careful conventional calibration [1, 7, 11, 29–31, 33, 34]. In physical thermometry, thermocouple drift is invariably a symptom of progressing inhomogeneity. Such change is progressive, often insidious, and usually is misinterpreted [34].

Rather than envisioned correctly as localized degradation of Seebeck coefficient, drift is often viewed improperly as a uniform “black-box” decalibration of the thermocouple rather than progressing inhomogeneity. For this reason, it is a far more commonplace problem than recognized by most experienced users. It can occur in use, in fabrication, or in calibration because of mechanical strain, thermal phase change, surface contamination, chemical interaction between materials, evaporation or migration of alloy constituents, transmutation under radiation, and a variety of other realistic causes.

Inhomogeneity error in thermocouples, as manufactured, is intended to be covered by standard tolerances [1, 9, 10, 28]. Troublesome inhomogeneity is most common in used and abused thermocouples, but can sometimes occur in new thermocouples that have been individually calibrated to high temperature. It can occur within and through apparently impervious protective metal sheaths or thermal wells and between bead insulators.

The example, Figure 32.30, illustrated the effect of improperly controlled junction temperatures that resulted in the subtle introduction of relative Seebeck emf from an unintended thermal pairing of segments of homogeneous thermoelements. The analogous inhomogeneity problem, best visualized with the $T/X$ sketch, arises when a portion of one or both thermoelements locally changes in Seebeck coefficient over some nonisothermal span of the thermocouple. In effect, this introduces phantom dissimilar segments of indefinite graduated property and unrecognized location [35]. This most often occurs over a lengthy region near the measuring junction where the thermoelements are exposed to damaging environments in an oven or process.

The maximum possible error of inhomogeneity is determined by the location and magnitude of greatest deviation from normal of the Seebeck coefficient. The actual error depends on the momentary distribution of temperature during use. In thermometry and in calibration, the likely error introduced by inhomogeneity is moderated. While present only within an isothermal region, inhomogeneities introduce no error. Under unfavorable temperature distributions, inhomogeneity error can be extreme and results in peculiar puzzling responses [34]. Changes of relative Seebeck coefficient by more than 60% over 25-cm spans have been observed in individually calibrated, certified, premium-grade fine wire Type R MIMS thermocouples entirely enclosed within intact platinum sheaths and exposed to temperature within the tabulated temperature range [18].
Testing for Inhomogeneity

Many authentic sensitive and accurate tests for thermoelectric inhomogeneity have been developed, and their practical need has been demonstrated; however, they are rarely used [33]. All true inhomogeneity tests require moving an abrupt step of temperature progressively along thermoelements.

The commonplace application of a very narrow symmetric temperature pattern is the antithesis of an inhomogeneity test. It is not a test for inhomogeneity. Its popular use has misled many to discount inhomogeneity as a real and significant problem in accurate thermoelectric thermometry.

Valid tests range from simple methods of low resolution to advanced methods that can accurately resolve inhomogeneity with spatial resolution of a few millimeters [21, 33]. Regrettably, as inhomogeneity errors usually are not recognized, inhomogeneity is not authentically tested in commercial practice nor by calibration laboratories. Nevertheless, invalid though certified NIST-traceable certification to great precision is possible on a thermocouple that can be accurately measured to be severely inhomogeneous and of indefinite uncertainty [29–31, 33, 34].

Calibration

The measurement uncertainty of most kinds of sensors can be reduced by individual calibration. Initial calibration, periodic recalibration of unused thermocouples, and even of degraded individual thermocouples, although commonplace, is often less beneficial (or even harmful) and more costly. Such ill-advised thermocouple calibration has been mandated by some “quality assurance” programs.

Surveys reveal a trend for customers to demand progressively higher accuracy of thermometry [36]. In some applications, a 1°F (0.56°C) error now is deemed too large, and 0.1°F tolerance may be specified independent of temperature level. (Compare with tolerances in Table 32.12.) There are a few industrial applications that truly require such accuracy. More often, the specification merely presumes that such accuracy in thermocouple thermometry is routinely attainable merely by calibration. Calibration is an opiate of quality assurance. The illusion of accuracy provided by NIST-traceable certified calibration and purported in situ calibration is counterproductive if it is not authentic.

Consideration of the details of thermocouple calibration suggests why authentic accuracy at the 0.1°C level is unlikely in industrial thermoelectric thermometry. The approach to achieving authentic calibration of thermocouple system accuracy (ignoring thermal coupling and transient response errors) is illustrated in Figure 32.31. Figure 32.31(a) represents the thermocouple system to be calibrated. Calibration for thermoelectric thermometry must distinguish three system components: (1) the thermocouple circuit, (2) the reference junction temperature compensator, and (3) the monitoring instrument. Each separately affects temperature uncertainty.

The Principal Thermocouple

Calibration of principal thermocouples is performed by immersing the vicinity of the measuring junction in the isothermal region of a bath or oven [37]. Several compact dry-well calibrators available are convenient for calibration at the job site [38]. Fixed-point cells, liquid baths, and fluidized solid beds can be more accurate and are widely used in the calibration laboratory [39]. Sufficient depth of immersion into an isothermal calibration zone, usually at least 10 to 20 times the probe diameter, ensures that conduction of heat along the thermocouple from the environment does not affect the junction temperature.

The appropriate concern for the effect of longitudinal heat conduction on measuring junction temperature has led to the misperception that it is the junction that is being calibrated [30]. Clearly, thermocouple calibration is not of the measuring junction; it is of unidentified segments of thermoelements, remote from the measuring junction, only where they enter the isothermal calibration zone through a temperature transition.

Segments of service-induced inhomogeneity that seriously degrade measurement accuracy are often placed, during unsuccessful attempted recalibration, within the isothermal region where they contribute no Seebeck emf, so inhomogeneity is not discovered. The act of calibration at temperatures above 400°C can actually induce inhomogeneity and degrade accuracy [9, 10]. Not even costly “NIST-traceable”
calibration and certification by competent calibration laboratories, without specific assurance of homogeneity, are a guarantee of accuracy at any level.

Commercial Tolerances. Standardized tolerances for new thermocouple materials are established by the formal consensus judgment of many experienced producers, users, and calibration standards laboratories staff [10, 24, 28]. The tolerances include not only deviation from the overall Seebeck properties, but also cover inevitable uncertainty from inhomogeneity and irregular deviations from the smoothed standardized characteristic over small spans of temperature. They apply to material as delivered and not exposed to excessive temperature. The conservative tolerances for standard letter-designated thermocouple types as delivered are usually reliable until the thermocouples are exposed too long to excessive temperatures or adverse environments. Recalibration of used thermocouples without separate assurance of homogeneity can be misleading [31].

To address calibration problems presented by undiscovered inhomogeneity, two practices are common. For inexpensive base metal thermocouples, it is presumed that unused thermocouples are homogeneous and uniform within standardized tolerances. The typical Seebeck property of a production batch is characterized by the manufacturer or user by calibrating one or more expended surrogate samples. These are discarded after calibration. Their first-cycle calibration is taken as representative of other thermocouples of the same batch. Used principal thermocouples that have experienced drift are discarded.

A commonplace second approach is recalibration. This is usually in response to drift observed in service. Drift signals progressing inhomogeneity. Apart from an authentic inhomogeneity prescreening, recalibration is not recommended. Even widely promoted in situ recalibration of degraded thermocouples is ineffective if temperature distribution will vary in use [31].

Platinum-based thermocouple wire can be annealed full length by electrically heating in air [9–12]. Such annealed thermoelements can be presumed to be free of reversible strain-induced inhomogeneity and, thus, accurate recalibration might be justified. However, annealing cannot reverse decalibration from the migration, absorption, or evaporation of alloy constituents or other chemical contamination; therefore, recalibration, even of used precious metal thermocouples, should be performed only where the likelihood of homogeneity is factually based. Unlike base metal thermoelements, precious metal

![FIGURE 32.31 Contributions of Seebeck and compensating emf in system calibration: (a) the circuit to be calibrated or simulated, (b) a general calibration simulation of a system that includes internal reference junction temperature compensation.](image)

© 1999 by CRC Press LLC
thermoelement materials often can be reconditioned. Also, precious metals have a significant material salvage value if recycled.

**Extension Leads**

Compensating extension leads, although Seebeck sources, usually are not calibrated. It is commonly assumed that they will be exposed to only a small fraction of the temperature span that is being measured and, if so, will contribute insignificantly to error. Extension insulations are rated for continuous use to maximum temperatures between 105°C and 540°C [43]. Seebeck characteristics might not be well approximated over this range [1, 10]. The possible contribution from extensions can be very large. The plausible error is easily estimated using the model in “The Functional Model of Thermoelectric Circuits.” The more usual consequential errors due to extension leads result from failure to correctly control the temperatures of incidental splice junctions, as described in “Practical Thermocouple Circuits.”

**Reference Temperature Compensation**

Modern thermocouple indicators usually provide internal reference junction temperature compensation. A few make compensation a selectable alternative. The accuracy of reference junction compensation, Figure 32.31(a), depends on the accuracy of the sensor(s), f, used to monitor reference junction temperature of isothermal terminations, but also on the conformity of the scaling algorithm or analog circuitry to the characteristic of the individual thermocouple. The zone sensor determines the compensating voltage, $E_z$. Some monitors have replaceable isothermal terminal blocks that include the zone temperature sensor. Most monitor designs unfortunately do not allow separate thermal calibration of the reference temperature sensor. Simply shorting the indicator input terminals, b-d, should produce a temperature indication near, and usually slightly above, ambient temperature. Specifications claim reference uncertainty on the order of 0.1°C to 0.5°C and error contributions usually are small but infrequently they have been very large and insidiously progressive up to many times the standard thermocouple tolerances [35].

**Monitoring Instruments**

The accuracy of conversion of the Seebeck voltage at terminals b-d to deduce the temperature $T_c$ requires calibration of the monitoring instrument. Both the accuracy of voltage measurement and of linearization are sources of uncertainty. The scaling accuracy is based on an approximation of the defining $E(T)$, and not on the individual thermocouple characteristic.

Instrument designs are varied. The general principles of authentic calibration required to approach 0.1°C uncertainty for a thermocouple indicator that provides internal reference temperature compensation are illustrated with the circuit of Figure 32.31(b). A thermocouple simulator/calibrator supplies a well-known voltage $E_s$ that corresponds, for the standard thermocouple type, to a desired temperature calibration point. The simulator must remain in thermal equilibrium during calibration, with irrelevant Seebeck voltage properly nulled.

If the input resistance of the indicator is very large, resistance matching of the simulator to the thermocouple is not required. If the indicator has a low input resistance or it internally produces current $i$ when its terminals b-d are shorted, then a temperature error proportional to the indicator current and the loop resistance will be experienced. For accuracy with such indicators, the simulator $R_s$ must also mimic the source resistance of the individual thermocouple ($R_A + R_B$). However, that thermocouple loop resistance may vary considerably in application as it depends on the temperature distribution around the thermocouple over a broad range of temperatures.

The input terminals of the indicator are b and d. For accurate calibration, it is essential that $T_b = T_d = T_z$. Some indicators and reference temperature compensators connect the isothermal zone block to the terminals with compensating thermocouple leads. For these, if $T_b \neq T_d \neq T_z$, an indefinite error results that cannot be overcome by calibration.

The simulator voltage must imitate the behavior of only the thermocouple, b-c-d. The voltage it must provide depends on whether or not the indicator supplies internal reference temperature compensation.

If $T_b = T_d = T_z$, the proper total Seebeck voltage is $E_{AB/5^\circC} = E_{AB/0^\circC} + E_{AB/5^\circC}$. If the indicator does not apply
reference temperature compensation, $E_r$, then the simulator must provide $E_s = E_{sh}^B + E_r$. If the indicator does apply $E_r$, then the simulator must supply only $E_s = E_{sh}^B$.

This requires that the internal $T_z$ of the indicator be accurately known by the simulator. Some simulators allow setting a presumed $T_z$ in calibration. Those that do not cannot be used directly without error for calibration of the commonplace reference temperature compensating indicators. Many convenient thermocouple instrument calibrators allow setting the desired calibration by temperature rather than by voltage for standardized thermocouple types. This convenience introduces an additional nonlinear scaling and only approximate conformity to the standard characteristic.

**Thermocouple Failure and Validation**

A thermocouple measurement has failed when its indications are beyond uncertainty limits required for a measurement. Thermocouples sometimes fail “open” as junctions separate or thermoelements corrode, yield, or melt. Explicit “open circuit” indication is a promoted feature of many modern thermocouple indicators. This popular indication is useful, but is not an adequate indicator of thermocouple integrity.

The more common but less apparent circuit failures are by inobvious shunting, shorting, or progressing inhomogeneity of thermoelements. These are not detected by the “open circuit” indication. The continual indication of a plausible temperature is not proof of authentic temperature measurement.

A deliberate or accidental electrical shunting or direct short between thermoelements at ambient temperature local to an electronic compensating reference junction should result in an indication near ambient temperature, not $0^\circ C$. A thermocouple failure resulting from direct shorting between thermoelements at some distance from the intended measuring or reference junctions can go undetected because it occurs in a temperature region that is very different from the reference temperature and where a valid or plausible temperature measurement can continue to be made but at an irrelevant and unexpected and unrecognized location [35]. In some situations, as in predictably hostile environments, such failure of some thermocouples in service is anticipated. Where the failure is because of thermocouple circuit damage, it may not be evident immediately (or ever) without special circuit diagnostics. For such critical situations, special thermoelectric circuits and monitoring methods have been developed to assess the continued circuit integrity, although not the accuracy, of thermometry [35].

**Environmental Compatibility**

A primary consideration in thermocouple selection is compatibility of the thermoelements with their protective enclosures and of both thermoelements with the environment of measurement. Thermoelements must be protected from corrosive environments and electrically conductive fluid or solid shunts. Plastic, ceramic, or fiber insulators, metallic sheaths, and thermowells are intended to serve this function but may fail in service [1, 9–12, 25]. The compressed granular insulation of mineral-insulated, metal-sheathed thermocouples, if exposed, rapidly absorbs moisture that can seriously degrade resistive isolation [1, 10–12]. When cut, ends of MIMS thermocouple sheaths must be quickly resealed to avoid moisture absorption. Fiber and bead insulators are easily contaminated and can degrade accuracy [1, 10].

**Temperature Exposure**

The unavoidable environmental variables in thermometry are temperature and duration. Although thermoelements may not be visibly affected by an environment, the Seebeck coefficient might be substantially degraded. Even if only a very thin surface layer of a thermoelement is modified, the Seebeck coefficient could be changed. The properties can be degraded by use for a long period of time, at extreme temperatures, and in adverse environments [1, 9–12]. For these reasons, application should be limited to within the suggested temperature limits (Table 32.15). Calibration should be performed quickly, allowing time only for equilibration, and only to the maximum temperature of intended use. Degradation, observed in use as instability or drift, is necessarily a symptom of progressing inhomogeneity [30, 31].

Sustained excessive temperature alone can quickly degrade a thermoelement. Melting points define the absolute upper temperature range of thermocouple use. However, below this definite value, there are
indirect application limits at which stability might be substantially reduced [1, 9–12]. Standard thermocouple tables extend only to the greatest temperature of recommended use for benign protected environments, short durations, and for wire materials of 3 mm or greater diameter [1, 9, 10]. Significantly reduced temperature limits apply for materials of smaller cross-section, Table 32.14 [1]. The thermocouples of smaller cross-section degrade more quickly. The standard tolerances apply only to material as manufactured.

**Chemical Environment**

There are broad guidelines for environmental compatibility. These recommendations are conditional and critically depend on many specifics of exposure. A concise summary of environmental compatibility characteristics is given in Table 32.16. The references should be consulted for detailed compatibility information [1, 4, 9, 22, 23]. Many thermocouple catalogs include tables of usually tolerable chemical environments for thermoelements or thermowell materials [19, 20]. Service experience in working with customers in a wide variety of process environments sometimes enables manufacturers to advise users on special problems of compatibility. Often, suitability in a particular service can be assured only by trial.

**Metallurgical Change**

Alloyed thermoelements can locally change composition by evaporation of constituents when exposed to vacuum. Alloy constituents evaporated from a sheath or from one thermoelement can deposit and coat adjacent thermoelements even through insulators [1, 9–12, 24, 30, 31]. Alloy components can migrate from one thermoelement to the other through the measuring junction. Traces of contaminants can penetrate through pinholes and hairline cracks and can actually diffuse through intact protective

sheaths and affect apparently isolated thermoelements. Minute trace impurities in sheaths or insulating materials can interact with thermoelements. Appropriate MIMS construction and material selection usually extends life and increases temperature limits, but damage can occur even within apparently fully sheathed assemblies [34]. Excessive strain can locally substantially modify the Seebeck coefficient of one or both thermoelements resulting in inhomogeneity. Very localized strain, as introduced by sharp bends, usually has little effect on practical thermometry.

Data Acquisition

Thermocouple Indicators

The instrument designer can shelter the user from many troublesome details that complicated measurement for thermocouple pioneers. Microvolt-level signal resolution, high input resistance, stability, noise reduction, nonlinear scaling, and reference temperature compensation are now routinely provided to allow the user to focus on the measurement rather than on details of its indication or recording.

Some thermocouple indicators are hand-held and accommodate only a single thermocouple and only of a single type. A few provide dual thermocouple inputs and allow direct differential temperature measurement for which reference junction compensation must not be directly applied. Other bench-top units accommodate several thermocouple inputs of the same or of intermixed thermocouple and other sensor types.

Claimed instrument accuracy could mislead the casual reader. Although many instruments are supplied complete with a thermocouple probe, some accuracy specifications describe only the accuracy of input terminal voltage measurement. The actual instrument accuracy should be determined by electrical calibration (see “Calibration” section). Occasionally, the error of the indicating instrument becomes substantially greater than specified due to drift of reference compensation, offset, or gain. The additional uncertainty of thermocouple calibration, Table 32.13, and the often larger discrepancy between measuring junction temperature and the actual temperature of the object being measured, cannot be included because the latter are governed by details of heat transfer and transient thermal response.

Thermocouple Transmitters

A less familiar form of thermocouple signal conditioning, the thermocouple transmitter, is commonplace in process industries [4, 39]. Most two-wire thermocouple transmitters (not an RF wireless transmitter) are single-channel devices that perform reference junction compensation, linearizing, and isolation, and transmit the conditioned information to a remote monitoring site [1]. The transmitter converts the temperature-scaled Seebeck emf to an analogous signal for wire transmission over long lines to a remote recording or monitoring location. Such inexpensive and compact single-sensor signal conditioners are available specialized to most process variables. Thermocouple transmitters are well suited for monitoring slowly changing temperatures at monitoring sites distant from the measuring junction. Many are electrically isolated for safety. Some are adapted for use with the DIN rail mounting system. A transmitter can be installed near each thermocouple. Some are small enough to install in the connection head of a thermowell.

The transmitted signal can take either current-modulating or voltage-modulating form following ISA standards. The current-style transmitter temperature modulates, in proportion to temperature, a dc current supplied from the monitoring site. The signal ranges between 4 mA and 20 mA. The current-style transmitter conveys information over great distances without the voltage loss attendant to long-line voltage transmission. Some of the voltage-style transmitters modulate a supplied voltage over the span from 1 Vdc to 5 Vdc. Offset and scaling for some are adjusted at the transmitter. Some transmitters now have a local digital readout, and the scaling and offset can be remotely adjusted [4, 39].

Recording

Some multichannel thermocouple data recorders are now battery powered for stand-alone use and small enough to be hand held [41]. Some simpler recorders now cost less than U.S.$200. More sophisticated
units accommodate multiple thermocouples of the same or intermixed type. Larger digital data loggers with multiplexers that sequentially sample the output from individual thermocouples can accommodate up to several hundred inputs and can record a mix of both thermocouple and other signals at sample intervals programmable from a few milliseconds to hours or days. Desirable three-wire switching between thermocouples is commonplace.

Personal computers now accommodate inexpensive internal digital data acquisition boards that can convert the computer to a high-resolution temperature recording system. Laptop computers can accept special palm-sized PCMCIA plug-in cards for multiple thermocouple input. Digital computer based data acquisition systems with software specialized for data acquisition, analysis, and presentation, allow the user to apply special reference temperature compensation, customized linearization of thermocouple scaling functions for either standard or individual calibrations and of special thermocouple types. Computer-based thermocouple systems with suitable commercial data acquisition and other software, provide for experiment design, prediction, data acquisition, information management, analysis, reporting, archiving, and communication within a single compact fieldable laptop computer [42].

Signal Transmission

The length of the principal thermocouple should be as short as feasible. The thermoelements should be continuous between measuring junction and reference junctions for best accuracy, but lengthy extension cables can be used if necessary (see “Practical Thermocouple Circuits” section). In field experiments and in process monitoring, recording might be separated from the measuring junction by hundreds of meters. There are several satisfactory possibilities for signal transmission over great distances.

Extension Cable

Matching and compensating thermoelectric extension cables (see “Practical Thermocouple Circuits” section) are available in a wide variety of constructions and insulations [4, 43]. An extension cable, as a transmission line, can be a single twisted thermoelectric pair or a multipair cable designed for suppression of both electrostatic and electromagnetic noise and for environmental protection. While inexpensive unshielded insulated extension wire is available, in the common situation where electric noise is likely, each extension should be an insulated, individually shielded, and twisted pair. Where several extension pairs from a cluster of nearby thermocouples extend to a remote recorder, multipair thermoelectric cable is available that adds an overall electrostatic shield, mechanical strengthening reinforcement, and a robust environmental overjacket to protect from mechanical damage and chemical intrusion in harsh process environments [4, 42].

Such elaborate thermoelectric extension is more expensive than copper instrumentation cable; thus, alternative transmission systems should be considered. The proper use of twisted pair copper instrumentation cable as neutral extension leads, extending from external reference junction temperature compensation, can be sufficient and less costly than thermoelectric extensions.

Higher quality twisted-shielded-pair instrumentation cable can also improve signal fidelity in transient thermometry. For such neutral extension leads, insulated solid unplated copper instrumentation pair only should be used because nonuniform plating thickness can result in irregularly distributed inhomogeneity and cause Seebeck emf noise. Conventional coaxial instrumentation cable should never be used as lengthy neutral thermoelectric extension leads because the outer braid and center conductors have very different Seebeck coefficients. If not at uniform temperature, the cable can be a significant source of Seebeck noise emf.

Thermoelectric extensions and “pigtailed” assemblies should be checked full-length for hidden junctions between slightly mismatched spliced thermoelements and for deliberate, but hidden, pair splices incorrectly made in crossed polarity [10]. Pass a narrow heat source along the full length of the cable, while monitoring for local jumps of output local to such unintended junctions, using a thermocouple indicator. This test is very effective to pinpoint hidden junctions. It does not test for inhomogeneity [10, 30].
Optic fiber cable with electro-optic transmitters can be used for electric noise-free cable transmission over a long distance between signal conditioning that is local to the thermocouple and to a remote recorder or monitor.

**Wireless Transmission**

In several situations, copper wire transmission is less effective, more expensive, or less convenient than wireless methods. Several low-cost wireless (not thermocouple transmitter) data acquisition systems are now adapted to combine thermocouple data acquisition and remote signal transmission [44]. Radio modems communicate data from a measuring location to recording sites as much as 5 km away. Most provide spread spectrum transmission that does not require a communications license. Wireless data transmission can be particularly economical where the distance between the measuring junction and recorder is great, when many thermocouples must be recorded, when little setup time is available for field cabling, and where the measuring setup must be moved occasionally. Some systems combine data logging and radio communication in a single unit. Others require the use of a thermocouple transmitter, a data logger, and the radio modem to form a system.

**Sources of Thermocouple Application Information**

**Technical Papers**

The most concentrated and broadest sources of refereed technical papers addressing thermocouple thermometry are the serial proceedings of a decennial international symposium on temperature [25]. The six volumes to date are a rich and reliable source of application data. Proceedings of annual symposia of the ISA and NCSL also have a few papers describing current developments in thermometry. Reference [26] has thermoelectric data on the widest variety of common and nonstandard materials. Current papers devoted specifically, not incidentally, to thermocouples are infrequent and are distributed broadly across trade magazines and journals of professional societies. Essential details of thermocouple thermometry are more often (poorly) described only incidentally in reports of experimental studies. Some manufacturers publish subscription technical journals specializing in thermometry [45].

One measurement journal frequently publishes articles on applied thermometry and, annually in the June issue, publishes an extensive directory of manufacturers of thermocouple materials and related instrumentation [46]. The directory includes, for several dozen listed manufacturers, concise descriptions of selected products and current prices.

**Books, Reports, and Standards**

A very detailed and authoritative NIST monograph is the primary source for Seebeck properties and physical characteristics of letter-designated thermocouples [9]. Standards of the ASTM and ISA adopt the values and complement the NIST report [10, 24]. U.S. standards are reviewed and updated at intervals of 5 years or less. The ASTM also publishes interim tables of Seebeck emf for a few popular materials that have not been standardized [10]. Many standards are collected in a single, annually revised volume specializing in thermometry [10]. The hardcopy thermocouple tables from these volumes are now available as functional computer programs that calculate $E(T)$ and $T(E)$ of the NIST 175 document over ranges, at intervals, and in units selected by the user [46].

A comprehensive thermocouple application manual is published by the ASTM [1]. Many commercial publishers issue new reference and textbooks addressing measurement. Most of these include a brief obligatory section or chapter describing the bare elements of thermocouple thermometry. A few devote an entire volume to thermometry. There are many deeper scientific treatments of thermoelectricity, mostly in the historic literature [1, 11, 12].

Many national and international consensus standards organizations publish thermoelectric test methods and material characterizations [10, 21, 25]. Standards are instructive as well as being formalizations of procedures and materials. ASTM Standards and indexes to them are now available in computer CD-ROM file format. Some standards now are available on the World Wide Web or by FAX. Societies
with committees that specialize in thermoelectric standards now have Internet Web sites (such as http://www.isa.org and astm.org) that provide information about available standards and solicit on-line technical questions from users.

Workshops
Annually, there are several excellent workshops of a few hours or days duration devoted to measurement, thermometry, and even thermocouples. Professional societies such as the ISA, in association with special symposia or annual meetings, present special tutorial workshops. Some are offered without fee by manufacturers. Other measurement courses are offered by independent measurement specialists. Announcements of these workshops are published in the technical and trade journals.

Trade Literature
Abundant, free, commercial catalog literature, handbooks, and Web site advertising describe thermocouple hardware and data acquisition products. Some manufacturers publish elaborate catalogs of thermocouple-related hardware, software, and books [4]. Most include tutorial material. A few include technical reprints, discussion of principles and practices, and present extensive tables of thermoelectric characteristics and physical properties of thermocouple materials. Demonstration programs and product information are available from manufacturers on CD-ROM and on the Internet. There are several trade journals that relate to measurement, explore current issues and developments, and are distributed free to qualified recipients.

Caveat
The reader is cautioned that the extensive current and historic literature of thermoelectric thermometry, tutorial articles (even this one), standards, specifications, and advice from “experts,” all must be studied very critically with an authentic thermoelectric model in mind. At every level of sophistication, from the promotional to the most esteemed esoteric and sophisticated mathematical and physical thermoelectric theory, innocently propagated misconceptions concerning the thermoelectric effects are very commonplace.

Summary
The Seebeck effect can be used to measure temperature with finer spatial and time resolution, over a broader temperature range, in more diverse geometries, and at lower cost than most other electric temperature sensors. The unique versatility of the thermocouple ensures that it will continue as the thermometry means of choice for many applications despite competition from an increasing variety and abundance of alternative special-purpose thermometers. However, the misleading seeming simplicity of the idealized thermocouple and the convenience and apparent accuracy afforded by modern signal conditioning instruments can be misleading. Correct application is simple.

Properly used within its limitations, the thermocouple is capable of accurate reliable thermometry. Improperly understood, the thermocouple is subject to misapplication and inconspicuous, but very significant, error. This precautionary overview described pitfalls and their avoidance in thermocouple practice. This can provide the receptive reader with an authentic basis for the knowledgeable use of even the most complex series and generalized thermoelectric circuits in circuit design, diverse applications, particularly in thermometry. The simple Functional Model presented here (and perhaps requiring some study) was deliberately crafted to aid the user in clearly distinguishing the authentic information from the misleading, and to aid in evaluating the designs and specifications of manufacturers of thermoelectric products.

### 32.5 Semiconductor Junction Thermometers

**Randy Frank**

Temperature sensors can be easily produced with semiconductor processing technology by using the temperature characteristics of the *pn junction*. The batch processing and well-defined manufacturing processes associated with semiconductor technology can provide low cost and consistent quality temperature sensors. The temperature sensitivity of the *pn junction* is part of the transistor’s defining equations and is quite predictable over the typical semiconductor operating range of −55°C to +150°C.

Most semiconductor junction temperature sensors use a diode-connected bipolar transistor (short-circuited collector-base junction) [1]. A constant current passed through the base-emitter junction produces a junction voltage between the base and emitter (*V*<sub>be</sub>) that is a linear function of the absolute temperature (Figure 32.32). The overall forward voltage drop has a temperature coefficient of approximately 2 mV °C<sup>−1</sup>.

When compared to a thermocouple or a resistive temperature device (RTD), the temperature coefficient of a semiconductor sensor is larger but still quite small. Also, the semiconductor sensor’s forward voltage has an offset that varies significantly from unit to unit. However, the semiconductor junction voltage vs. temperature is much more linear than that of a thermocouple or RTD. In addition to the
temperature-sensing element, circuitry is easily integrated to produce a monolithic temperature sensor with an output that can be easily interfaced to a microcontroller and to provide features that are useful in specific applications. For example, by using an embedded temperature sensor with additional circuitry, protection features can be added to integrated circuits (ICs). A temperature sensor becomes an embedded item in a semiconductor product when it has a secondary or supplemental purpose instead of the primary function.

The Transistor as a Temperature Sensor

A common semiconductor product for temperature sensing is a small-signal transistor such as a 2N2222 or a 2N3904. By selecting a narrow portion of the overall distribution of the $V_{be}$ for these devices, a temperature sensor with a lower variation in characteristics can be obtained. The lower variation can provide a part-for-part replacement when a tolerance of only a few percent is acceptable. This device (formerly offered as an MTS102 but no longer in production) demonstrates the performance characteristics of the transistor used as a temperature sensor [2].

As shown in Figure 32.33 [2], a silicon temperature sensor has a nominal output of 730 mV at –40°C and an output of 300 mV at 150°C. The narrowly specified $V_{be}$ ranges between 580 mV and 620 mV at 25°C. The linearity error, or variation from a straight line, of this device is shown in Figure 32.34 [2]. The total accuracy is within ±3.0 mV including nonlinearity which is typically within ±1°C in the range of –40°C to 150°C. These readings are made with a constant (collector) current of 0.1 mA, passing through the device to minimize the effect of self-heating of the junction. When the constant current applied is larger than 0.1 mA, the effect of self-heating in the device must be taken into account. The variation of the $V_{be}$ with current is shown in Figure 32.35 [2].

Thermal Properties of Semiconductors: Defining Equations

A constant forward current supplied through an ideal silicon $pn$ junction produces a forward voltage drop, $V_f$ [3, 4]:

$$V_f = V_{be} = \left( kT/q \right) \ln \left( I_f/I_A \right)$$  \hspace{1cm} (32.86)
FIGURE 32.33  Base–emitter voltage vs. ambient temperature for a silicon temperature sensor.

FIGURE 32.34  Linearity error (in mV) vs. temperature for a silicon temperature sensor.

FIGURE 32.35  Base–emitter voltage vs. collector–emitter current.
where $k = \text{Boltzmann's constant } (1.38 \times 10^{-23} \text{ J K}^{-1})$

$T = \text{Temperature (K)}$

$q = \text{Charge of electron } (1.6 \times 10^{-19} \text{ C})$

$I_F = \text{Forward current (A)}$

$I_S = \text{Junction's reverse saturation current (A)}$

For constant $I_S$, the junction voltage ($V_{be}$) would be directly proportional to absolute temperature. Unfortunately, $I_F$ is temperature dependent and varies with the cube of absolute temperature. As a result, $V_F$ has an overall temperature coefficient of approximately $-2 \text{mV °C}^{-1}$.

To reduce the temperature variation, a band gap reference is formed based on two adjacent and essentially identical-behavior transistors with proportional emitter area designed in an integrated circuit process. The two base–emitter junctions are biased with different current densities ($I/A$), but the ratio of current densities is essentially constant over the operating temperature range ($-55°C$ to $+150°C$). The following equation shows how the differential voltage ($\Delta V_{be}$) is related to the current ($I$) and emitter area ($A$) of the respective transistors:

$$V_{be1} - V_{be2} = \Delta V_{be} = \left(\frac{kT}{q}\ln\left(\frac{I_1}{A_1}\right)/\left(\frac{I_2}{A_2}\right)\right)$$

(32.87)

The differential voltage appearing at the output can be amplified as shown in Figure 32.36 and used as a direct indication of absolute temperature. Additional circuitry can eliminate the offset voltage at $0°C$ and provide an output in degrees Celsius or degrees Fahrenheit.

The ability to obtain temperature sensing using semiconductor processing techniques has two significant consequences: (1) semiconductor processing and integrated circuit design can be used to improve the temperature sensor’s performance for specific applications, and (2) temperature sensors can be integrated within other integrated circuits to obtain additional features. The next two sections explain these approaches.

**Integrated Temperature Sensors**

Once a temperature sensor can be manufactured using semiconductor processing techniques, a number of shortcomings of the sensor can be corrected by additional circuitry integrated into the sensor or by using circuit techniques external to the sensor. The linearity improvement, addition of precision voltage references, precision voltage amplifiers, and digital output for direct interface to a microcontroller (MCU)

\[ \text{FIGURE 32.36} \quad \text{Differential pair formed by two } pn \text{ junctions. The transistors are diode connected to form a temperature sensor independent of variations in source current.} \]
are among the enhancements possible. Furthermore, resistance-measuring circuitry (i.e., RTD sensors) or cold junction compensation (i.e., thermocouple sensors) are not required. Three integrated circuits and one external circuit example are discussed.

**Integrated Digital Temperature Sensor**

A *monolithic* (one piece of silicon) semiconductor junction temperature sensor (LM75 from National Semiconductor) that incorporates several features, including a digital output, is shown in Figure 32.37 [3]. The analog signal of the temperature sensor is converted to digital format by an on-board sigma–delta converter [3]. Digital communication is provided directly to a host microcontroller through a serial two-wire interface. The sensor has a software-programmable setpoint that can be used to terminate the operation of the controller or implementing protection [5]. To avoid false triggering, a user-programmable number of comparisons (up to six successive over-temperature occurrences) can be implemented.

Eight different sensors can be operated on the bus. Resolution is \( \pm 1/2^\circ C \) and the accuracy is \( \pm 2\% \) from \(-25^\circ C\) to \(+100^\circ C\). The sensor consumes 250 \( \mu A \) during operation and only 10 \( \mu A \) in sleep mode.

**Analog Output Integrated Temperature Sensor**

Another approach to integrated temperature sensing is shown in Figure 32.38 [4]. The TMP-1 resistor-programmable temperature controller features a 5-mV \( ^\circ C^{-1} \) output high and low set points and over- and under-temperature output. A low-drift voltage reference is also included in the 70 mil \( \times \) 78 mil (2.76 mm \( \times \) 3.07 mm) design. Figure 32.39 shows a photomicrograph of the silicon die. The TMP-1 is specified for operation between \(-55^\circ C\) and \(+125^\circ C\), with \( \pm 1^\circ C \) accuracy over the entire range.

**Digital Output Temperature Sensor**

A direct-to-digital temperature sensor has been designed for multi-drop temperature sensing applications [6]. A unique serial number is etched onto each device. The 64-bit read-only memory (ROM) identifies the temperature of a particular sensor in a measurement system, with several sensors providing readings from different locations. The signal can be transmitted for distances up to 300 m.
The temperature sensor operates from –55°C to 125°C with the power supplied from the data line. The measurement is resolved in 0.5°C increments as a 9-bit digital value, with the conversion occurring within 200 ms. User-definable alarm settings are included in the device.

External Circuitry Eliminates Calibration

External circuitry can be designed to utilize the inherent sensing capability of low-cost transistors without incurring the additional cost of integrated circuitry or the need to calibrate each device. The circuit shown in Figure 32.40 uses an integrated circuit (LTC1043 from Linear Technology Corporation) to provide a 0 V to 10 V output from 0°C to 100°C, with an accuracy of ±1°C using any common small signal transistor as the temperature sensor [7]. The circuitry establishes a $\Delta V_{be}$ vs. current relationship that is constant regardless of the $V_{be}$ diode’s absolute value. Substituting different transistors from multiple sources showed a variation of less than 0.4°C.

Other Applications of Semiconductor Sensing Techniques

Several semiconductor parameters vary linearly over the operating temperature range. Power MOSFETs used to switch high levels of current (typically several amperes) at voltages that can exceed 500 V provide an example of these characteristics. As shown in Figure 32.41 [8], the gate threshold voltage of a power MOSFET changes from 1.17 to 0.65 times its 25°C value when the temperature increases from −40°C to 150°C. Also, the breakdown voltage of the power MOSFET varies from 0.9 to 1.18 times its value at 25°C over the same temperature range (Figure 32.42) [8]. These relationships are frequently used to determine the junction temperature of a semiconductor component in actual circuit operation during the design phase (see “Reliability Implications”). External package level temperature measurements can be many degrees lower than the junction temperature, especially during rapid, high-energy switching events. The actual junction temperature and the resulting effect on semiconductor parameters must be taken into account for the proper application of semiconductor devices.

Polysilicon diodes (and resistors) that are isolated from the power MOSFET can be produced as part of the semiconductor manufacturing process with minor process modifications. The diodes can be used as temperature sensing elements in an actual application [9]. The thermal sensing that is performed by the polysilicon elements is a significant improvement over power device temperature sensing that is performed by an external temperature sensing element. By sensing with polysilicon diodes, the sensor can be located close to the center of the power device near the source bond pads where the current

---

FIGURE 32.40  External circuitry provides $\Delta V_{be}$-based thermometer that does not require calibration. (Courtesy of Linear Technologies Corporation.)
density is the highest and, consequently, the highest die temperature occurs. The thermal conductivity of the oxide that separates the polysilicon diodes from the power device is 2 orders of magnitude less than that of silicon. However, because the layer is thin, the polysilicon element offers an accurate indication of the actual peak junction temperature.

A power FET that incorporates temperature sensing diodes is shown in Figure 32.43 [9]. By monitoring the output voltage when a constant current is passed through the integrated polysilicon diode(s), an accurate indication of the maximum die temperature is obtained. A number of diodes are actually provided in the design. A single diode in this design has a temperature coefficient of 1.90 mV °C⁻¹. Two or more can be placed in series if a larger output is desired. For greater accuracy, the diodes can be trimmed during wafer-level testing by blowing fusible links made from polysilicon. The response time of the diodes is less than 100 µs, which has allowed the device to withstand a direct connection across an automobile battery with external circuitry providing shutdown prior to device failure. The sensing capability also allows the output device to provide an indication (with additional external circuitry) if the heatsinking is not proper when the unit is installed in a module or if a change occurs in the application that would ultimately cause a failure.
Temperature Sensing in Power ICs for Fault Protection and Diagnostics

Sensing for fault conditions, such as a short-circuit, is an integral part of many smart power (or power) ICs. The ability to obtain temperature sensors in the semiconductor process provides protection and diagnostics as part of the features of these devices. The primary function of the power IC is to provide a microcontroller-to-load interface for a variety of loads. In multiple output devices, sensing the junction temperature of each device allows the status of each device to be provided to the microcontroller (MCU), and, if necessary, the MCU can shut down a particular unit that has a fault condition.

A smart power IC can have multiple power drivers integrated on a single monolithic piece of silicon [10]. Each of these drivers can have a temperature sensor integrated to determine the proper operating status and shut off only a specific driver if a fault occurs. Figure 32.44 shows an eight-output driver that independently shuts down the output of a particular driver if its temperature is excessive (i.e., between 155°C and 185°C) [10].

The octal serial switch (OSS) adds independent thermal sensing through over-temperature detection circuitry to the protection features. Faults can be detected for each output device, and individual shut-down can be implemented. In a multiple output power IC, it is highly desirable to shut down only the device that is experiencing a fault condition and not all of the devices that are integrated on the power IC. With outputs in various physical locations on the chip, it is difficult to predict the thermal gradients that could occur in a fault situation. Local temperature sensing at each output, instead of a single global temperature sensor, is required.

As shown in Figure 32.45, the eight outputs of the device with individual temperature sensors can be independently shut down when the thermal limit of 170°C is exceeded [10]. All of the outputs were connected to a 16-V supply at a room temperature ambient. A total current of almost 30 A initially flowed through the device. Note that each device turns off independently. The hottest device turns off first. Variations can result from differences in current level and thermal resistance. As each device turns off, the total power dissipation in the chip decreases and the devices that are still on can dissipate heat more effectively.
Connecting directly to the battery is a hard short that could have been detected by current limit circuitry. However, a soft short is below the current limit, but exceeds the power-dissipating capability of the chip, and can be an extremely difficult condition to detect. Soft shorts require over-temperature sensing to protect the IC from destructive temperature levels.

The over-temperature condition sensed by the power IC could mean that the device turns itself off to prevent failure in one case; and in another situation, a fault signal provides a warning to the MCU but no action is taken, depending on the fault circuit design. The remaining portion of the system is allowed to function normally. With the fault conditions supplied to the MCU, an orderly system shutdown can be implemented. Integrated temperature sensing is essential to provide this type of protection in a multiple-output power IC.

FIGURE 32.44 Photomicrograph of eight-output power IC. Note that the area of the eight output devices (two located at each corner of the die) are considerably larger than the circuitry in the center, and top and bottom that provides the temperature sensing, signal conditioning, and other control features. (Courtesy of Motorola, Inc.)
Reliability Implications of Temperature to Electronic Components

The effect of temperature on electronic components and their successful application in electronic systems is one of the issues that must be addressed during the design of the system. Temperature affects the performance and expected life of semiconductor components. Mechanical stress created by different coefficients of thermal expansion can cause failures in thermal cycling tests (air-to-air) or during thermal shock (water-to-water) transitions.

The typical failure rate for semiconductor components can be expressed by the Arrhenius equation [9]:

$$\lambda = Ae^{-\frac{\phi}{KT}}$$  \hspace{1cm} (32.88)

where

- $\lambda$ = Failure rate
- $A$ = Constant
- $\phi$ = Activation energy (eV)
- $K$ = Boltzmann’s constant ($8.62 \times 10^{-5}$ eV K$^{-1}$)
- $T$ = Junction temperature (K)

The failure rate of semiconductor components is typically stated to double for every 10 to 15°C increase in operating (i.e., junction) temperature. However, increased testing and design improvements have minimized the failures due to specific failure mechanisms.

One of the temperature-related parameters that must be taken into account during the design phase of a power switch is the transient thermal response, which is designated as $r(t) R_{thC}$, where $r(t)$ represents the normalized transient thermal resistance. The value of $r(t)$ is determined from the semiconductor manufacturer’s data sheet using duty cycle and pulse duration used in the application. This reduced level of the thermal resistance (see “Junction Temperature Measurement”), based on the transistor operating in a switching mode and being off for a period of time, approaches the dc level within a second. Excessive temperatures can be generated quickly and must be detected within milliseconds to prevent failure.
Junction Temperature Measurement

In a semiconductor, the change in temperature is directly related to the power dissipated through the thermal resistance. The steady-state dc thermal resistance junction-to-case, $R_{thJC}$, is defined as the temperature rise per unit power above an external reference point (typically the case). The relationship is shown in Equation 32.89 [8].

$$R_{thJC} = \frac{\Delta T}{P_d}$$  \hspace{1cm} (32.89)

where $\Delta T$ = Junction temperature minus the case temperature (°C)
$P_d$ = Power dissipated in the junction (W)

The semiconductor device or silicon die is typically enclosed in a package that prevents a direct measurement of the junction temperature. The junction temperature is measured indirectly by measuring the case temperature, $T_C$; the heatsink temperature, $T_S$; for those higher-power applications that require a heatsink; the ambient temperature, $T_A$; and a temperature-sensitive electrical parameter of the device.

The first step of the process requires calibrating the temperature-sensitive parameter. Using a bipolar power transistor as an example, the base-emitter forward voltage is measured and recorded with a low calibration current ($I_{M}$) flowing through the device that is low enough to avoid self-heating (typically between 2 mA and 10 mA) and yet sufficiently high to be in the linear range of the forward voltage curve.

After calibration, a power switching fixture (such as Figure 32.46) is used to alternately apply and interrupt the power to the device [8]. The on portion is long (typically several milliseconds) and the off portion is short (only a few 100 μs), so the temperature of the case is stabilized and junction cooling is minimal. The transistor is operated in its active region and the power dissipation is varied by adjusting the $I_e$ and/or $V_{CE}$ until the junction is at the calibration temperature. This point is known by measuring $V_{BE}$ during the time that $I_M$ is the only current flowing.

When the $V_{BE}$ value equals the value on the calibration curve, the junction temperature is at the calibration temperature. Measurements of $V_{BE}$, $T_C$, and $I_e$ allow the thermal resistance for the device to
be calculated using Equation 32.89. Since $R_{JC}$ is a constant, subsequent measurements of $T_C$, $V_{CE}$, and $I_E$ under different operating conditions can be used to calculate the junction temperature to keep the device within its safe operating range in the actual application. For devices with different electrical characteristics, such as the power MOSFETs discussed earlier, other parameters that have a linear relationship to temperature are used for calibration and measurement.

**Semiconductor Temperature Sensor Packaging**

Temperature sensors that are manufactured using semiconductor technology are typically packaged in packages common to the semiconductor industry. These include metal can (TO-99), ceramic, and more commonly available plastic (SOT-23, 8-lead DIP, TO-92, 8-lead SOIC, etc.) packages. These packages are designed for circuit board solder attachment that can be either through-hole or surface-mount technology. As a result, package form factors can be considerably different from packages for temperature sensors manufactured using other technologies. Figure 32.47 shows examples of five available silicon temperature sensor packages.

**Defining Terms**

**Bandgap reference:** Forward-biased emitter junction characteristics of adjacent transistors used to provide an output voltage with zero temperature coefficient.

**Die:** An unpackaged semiconductor chip separated from the wafer.

**Embedded sensor:** A sensor included within an integrated circuit.

**Integrated circuit:** A multiplicity of transistors, as well as diodes, resistors, capacitors, etc., on the same silicon die.

**Junction:** The interface at which the conductivity type of a material changes from $p$ type to $n$ type.

**Junction voltage:** The voltage drop across a forward-biased $pn$ interface in a transistor ($V_{be}$) or diode.

**Junction temperature:** The temperature of the $pn$ interface in a transistor or diode.

**Monolithic (integrated circuit):** Constructed from a single piece of silicon.

**Power IC or smart power IC:** Hybrid or monolithic (semiconductor) device that is capable of being conduction-cooled, performs signal conditioning, and includes a power control function such as fault management and/or diagnostics.

**Self-heating:** Temperature rise within a (semiconductor) device caused by current flowing in the device.

**Soft short:** An excessive load condition that causes excessive temperature but is below the current limit of a device.

**Thermal resistance:** The steady-state dc thermal resistance junction-to-case, $R_{JC}$, is the temperature rise per unit power above an external reference point (typically the case).

**TinyPak:** A trademark of National Semiconductor Corp.

Thermal Radiation: Physical Laws

In any material object, every atom and every molecule exist in perpetual motion. When an atom moves, it collides with other atoms and transfers to them part of its kinetic energy, thus losing some of its own energy in this perpetual bouncing. On the other hand, an atom having a smaller kinetic energy, after a collision gains some energy. Afterward, the material body consisting of such agitated atoms reaches the energetic equilibrium where all atoms, while not vibrating with exactly the same intensity, still can be described by an average kinetic energy. Such an average kinetic energy of agitated particles is represented by the absolute temperature, which is measured in degrees kelvin. In other words, what is commonly called temperature, is a measure of the atomic motion.

According to the laws of electrodynamics, a moving electric charge (all atoms are made of electric charges) is associated with a variable electric field. The field, in turn, produces an alternating magnetic field. And again, when the magnetic field changes, it results in a coupled with it variable electric field, and so on. Thus, a moving particle becomes a source of electromagnetic field that propagates outwardly with the speed of light and is called thermal radiation. This radiation is governed by the laws of optics — it can be reflected, filtered, focused, etc. Also, it can be used to measure the object’s temperature.

Electromagnetic waves originating from mechanical movement of particles can be characterized by their intensities and wavelengths. Both of these characteristics relate to temperature; that is, the hotter the object, the shorter the wavelength. Very hot objects radiate electromagnetic energy in the visible portion of the spectrum — wavelengths between 0.4 µm (blue) and 0.7 µm (red). For example, a filament in an incandescent lamp is so hot that it radiates bright visible light. If such a lamp is controlled by a dimmer, the light intensity can be reduced by turning the knob and observing that the dimmed light becomes more yellowish, reddish, and finally disappears. Near the end of the dimmer control, the filament is still quite hot, yet one cannot see it because it emanates light in the invisible infrared spectral range — wavelengths greater than 0.8 µm. Cooler objects radiate light in the near-, mid-, and far-infrared spectral ranges, which one cannot see. For example, electromagnetic radiation emanating from human skin primarily is situated at wavelengths between 5 µm and 15 µm — in the mid- and far-infrared ranges and is not visible to human eyes; otherwise, we all would glow in the dark (sick people with fever would look even brighter). If one imagines that all atomic vibration stopped for some mysterious reason, no electromagnetic
radiation would be emanated. Such an imaginable but impossible event is characterized by infinitely cold
temperature, which is called absolute zero.

Because temperature is a measure of the average atomic kinetic energy, it is logical to assume that one
can determine the object’s temperature by measuring the intensity of the emanated electromagnetic
radiation or its spectral characteristics. This presumption is the basis for noncontact temperature mea-
surements that are known by various names, depending on the application: infrared thermometry, optical
pyrometry, radiation thermometry, etc. Pyrometry is derived from the Greek word pyr, which means fire,
and thus is more appropriate for measuring hot temperatures. For lower temperatures, infrared thermometry
is used interchangeably with term radiation thermometry.

**Planck’s Law**

A relationship between the magnitude of radiation at a particular wavelength $\lambda$ and absolute temperature $T$
is rather complex and is governed by Planck’s law, which was discovered in 1901. It establishes radiant
flux density $W_\lambda$ as power of electromagnetic radiation per unit of wavelength:

$$W_\lambda = \frac{\varepsilon(\lambda) C_1}{\pi \lambda^5 (e^{C_2/\lambda T} - 1)} \quad (32.90)$$

where $\varepsilon(\lambda) = \text{Emissivity of an object}$

$C_1 = 3.74 \times 10^{-12} \text{ Wcm}^2$ and $C_2 = 1.44 \text{ cmK}$ are Constants

$e^x = \text{Base of natural logarithms}$

Spectral densities for different temperatures are shown in Figure 32.48.

**FIGURE 32.48** Spectral densities calculated within a solid angle of 1 steradian for blackbody source ($\varepsilon = 1$) radiation
toward infinitely cold space (at absolute zero).
Wien’s Law

Equation 32.90 does not lend itself to a simple mathematical analysis and thus is approximated by a simplified version, which is known as Wien’s law:

\[
W_\lambda = \frac{C_1}{\pi} \varepsilon(\lambda) \lambda^{-5} e^{C_1/\lambda T} \tag{32.91}
\]

Because temperature is a statistical representation of an average kinetic energy, it determines the highest probability for the particles to vibrate with a specific frequency and to have a specific wavelength. This most probable wavelength follows from Wien’s law by equating to zero a first derivative of Equation 32.91. The result of the calculation is a wavelength near which most of the radiant power is concentrated when light is emanated toward infinitely cold space at absolute zero:

\[
\lambda_m = \frac{2898}{T} \tag{32.92}
\]

where \(\lambda_m\) is in \(\mu\text{m}\) and \(T\) in kelvin. Wien’s law states that the higher the temperature, the shorter the wavelength. This formula also defines the midpoint of spectral response of a pyrometer or infrared thermometer.

Stefan–Boltzmann Law

Theoretically, a thermal radiation bandwidth is infinitely wide. Yet, most of the emanated power is situated within quite a limited bandwidth. Also, one must account for the filtering properties of the real world windows used in instruments. In order to determine the total radiated power limited within a particular bandwidth, Equation 32.90 or 32.91 must be integrated within the limits from \(\lambda_1\) to \(\lambda_2\):

\[
\Phi_{\text{bo}} = \frac{1}{\pi} \int_{\lambda_1}^{\lambda_2} \frac{\varepsilon(\lambda) C_1 \lambda^{-5}}{e^{C_1/\lambda T} - 1} \, d\lambda \tag{32.93}
\]

This integral can be resolved only numerically or by approximation. For a narrow bandwidth (\(\lambda_1\) and \(\lambda_2\) are close to one another), the solution can be approximated by:

\[
\Phi_{\text{bo}} = k T^4 \tag{32.94}
\]

where \(k\) is constant and \(x = (12/\lambda_2)(1200/T)\). For example, in the visible portion of spectrum at \(\lambda_2 = 0.7 \, \mu\text{m}\) and for temperatures near 2000 K, the approximation is a 10th-order parabola. An approximation for a very broad bandwidth (\(\lambda_1 \to \infty\) or practically, when the range between \(\lambda_1\) and \(\lambda_2\) embrace well over 50% of the total radiated power) is a 4th-order parabola, which is known as the Stefan–Boltzmann law:

\[
\Phi_{\text{bo}} = A \varepsilon \sigma T^4 \tag{32.95}
\]

where \(\sigma = 5.67 \times 10^{-8} \, \text{W/m}^2\text{K}^4\) (Stefan–Boltzmann constant), and \(\varepsilon\) is assumed to be wavelength independent. It is seen that with an increase in temperature, the intensity of electromagnetic radiation \(\Phi_{\text{bo}}\) grows very fast due to the 4th power of \(T\).

Kirchhoff’s Law

While wavelengths of the radiated light are temperature dependent, the magnitude of radiation also is a function of the surface property. That property is called emissivity, \(\varepsilon\). Emissivity is measured on a scale
from 0 to 1. It is a ratio of electromagnetic flux that is emanated from a surface to the flux that would be emanated from the ideal emitter having the same temperature. Reflectivity, \( \rho \), and transparency, \( \gamma \), also on a scale from 0 to 1, show what portion of incident light is reflected and passed through, respectively. There is a fundamental equation that connects these three characteristics:

\[ \varepsilon + \gamma + \rho = 1 \]  \hspace{1cm} (32.96)

Equation (32.96) indicates that any one of the three properties of the material can be changed only at the expense of the others. As a result, for an opaque object (\( \gamma = 0 \)), reflectivity \( \rho \) and emissivity \( \varepsilon \) are connected by a simple relationship: \( \rho = 1 - \varepsilon \), which, for example, makes a mirror a good reflector but a poor emitter.

**Emissivity**

The emissivity of a material is a function of its dielectric constant and, subsequently, refractive index \( n \). It should be noted, however, that emissivity is generally wavelength dependent (Figure 32.49). For example, a white sheet of paper is very much reflective in the visible spectral range and emits no visible light. In the far-infrared spectral range, its reflectivity is low and emissivity is high (about 0.92), thus making paper a good emitter of thermal radiation. However, for many practical purposes in infrared thermometry, emissivity can be considered constant.

For nonpolarized far-infrared light in normal direction, emissivity can be expressed by the equation:

\[ \varepsilon = \frac{4n}{(n+1)^2} \]  \hspace{1cm} (32.97)

As a rule, emissivities of dielectrics are high and of metals are low. Due to the high emissivity of dielectrics, they lend themselves to easy and accurate noncontact temperature measurement. On the other hand, such measurements from nonoxidized metals are difficult, due to small amounts of emanated infrared flux. Table 32.17 gives typical emissivities of some opaque materials in a temperature range between 0°C and 100°C.
Unlike most solid bodies, gases in many cases are transparent to thermal radiation. When they absorb and emit radiation, they usually do so only in certain narrow spectral bands. Some gases, such as N₂, O₂, and others of nonpolar symmetrical molecular structure, are essentially transparent at low temperatures, while CO₂, H₂O, and various hydrocarbon gases radiate and absorb to an appreciable extent. When infrared light enters a layer of gas, its absorption has an exponential decay profile, governed by Beer’s law:

\[
\frac{\Phi_x}{\Phi_0} = e^{-\alpha \lambda x}
\]  

where \( \Phi_0 \) = Incident thermal flux  
\( \Phi_x \) = Flux at thickness x  
\( \alpha \lambda \) = Spectral coefficient of absorption

The above ratio is called a monochromatic transmissivity \( \gamma_x \) at a specific wavelength \( \lambda \). If gas is nonreflecting, then its emissivity is defined as:

\[
\varepsilon_x = 1 - \gamma_x = 1 - e^{-\alpha \lambda x}
\]  

It should be emphasized that since gases absorb only in narrow bands, emissivity and transmissivity (transparency) must be specified separately for any particular wavelength. For example, water vapor is highly absorptive at wavelengths of 1.4, 1.8, and 2.7 μm, and is very transparent at 1.6, 2.2, and 4 μm.

All non-metals are very good diffusive emitters of thermal radiation with a remarkably constant emissivity defined by Equation 32.97 within a solid angle of about ±70°. Beyond that angle, emissivity begins to decrease rapidly to zero with the angle approaching 90°. Near 90°, emissivity is very low. A typical calculated graph of the directional emissivity of non-metals into air is shown in Figure 32.50A. It should be emphasized that the above considerations are applicable only to wavelengths in the far

TABLE 32.17 Typical Emissivities of Different Materials (from 0 to 100°C)
infrared spectral range and are not true for visible light, since emissivity of thermal radiation is a result of electromagnetic effects that occur at an appreciable depth.

Metals behave quite differently. Their emissivities greatly depend on surface finish. Generally, polished metals are poor emitters within the solid angle of $\pm 70^\circ$, while their emissivity increases at larger angles (Figure 32.50B). Oxidized metals start behaving more and more like dielectrics with increasing thickness of oxides.

**Blackbody**

By definition, the highest possible emissivity is unity. It is attributed to the so-called blackbody — an ideal emitter of electromagnetic radiation. If the object is opaque ($\gamma = 0$) and nonreflective ($\rho = 0$) according to Equation 32.96, it becomes an ideal emitter and absorber of electromagnetic radiation. The name blackbody implies its appearance at normal room temperatures — indeed, it does look black because it is not transparent and not reflective at any wavelength. In reality, a blackbody does not exist, and any object with a nonunity emissivity often is called a graybody. A practical blackbody ($\varepsilon$ is about 0.99 or higher) is an essential tool for calibrating and verifying the accuracy of infrared thermometers.

**Cavity Effect**

To make a practical blackbody, a cavity effect is put to work. The effect appears when electromagnetic radiation is measured from a cavity of an object. For this purpose, a cavity means an opening in a concave void of a generally irregular shape whose inner wall temperature is uniform over an entire surface. The emissivity of a cavity opening dramatically increases, approaching unity at any wavelength, as compared with a flat surface. The cavity effect is especially pronounced when its inner walls have relatively high emissivity. Consider a non-metal cavity. All non-metals are diffuse emitters. Also, they are diffuse reflectors. It is assumed that the temperature and surface emissivity of the cavity are homogeneous over an entire area. The ideal emitter (blackbody) would emanate from area $a$, the infrared photon flux $\Phi_b = a\sigma T^4_b$. However, the object has the actual emissivity $\varepsilon_b$ and, as a result, the flux radiated from that area is smaller: $\Phi = \varepsilon_b \Phi_0$ (Figure 32.51). Flux emitted by other parts of the object toward area $a$ is also equal to $\Phi_b$ (because the object is thermally homogeneous, one can disregard the spatial distribution of flux). A substantial portion of that incident flux $\Phi_b$ is absorbed by the surface of area $a$, while a smaller part is diffusely reflected:

$$\Phi = \Phi_b + \Phi_p = \varepsilon_b \Phi_0 + (1 - \varepsilon_b) \Phi_0 = \varepsilon_b \Phi_0.$$  

and the combined radiated and reflected flux from area $a$ is:

$$\Phi = \Phi_r + \Phi = \varepsilon_b \Phi_0 + (1 - \varepsilon_b) \Phi_0 = (2 - \varepsilon_b) \varepsilon_b \Phi_0.$$  

---

**FIGURE 32.50** Spatial emissivities for non-metal (A) and a polished metal (B).
As a result, for a single reflection, the effective emissivity can be expressed as:

$$\varepsilon_e = \frac{\Phi}{\Phi_0} = \left(2 - \varepsilon_b\right)\varepsilon_b$$  \hspace{1cm} (32.102)

It follows from the above that due to a single reflection, a perceived (effective) emissivity of a cavity at its opening (aperture) is equal to the surface emissivity magnified by a factor of \((2 - \varepsilon_b)\). Of course, there may be more than one reflection of radiation before it exits the cavity. In other words, the incident on area \(a\) flux could already be a result of a combined effect from the reflectance and emittance at other parts of the cavity’s surface. For a cavity effect to work, the effective emissivity must be attributed only to the cavity opening (aperture) from which radiation escapes. If a sensor is inserted into the cavity facing its wall directly, the cavity effect could disappear and the emissivity would be close to that of a wall surface.

**Practical Blackbodies**

A practical blackbody can be fabricated in several ways. Copper is the best choice for the cavity body material, thanks to its high thermal conductivity, which helps to equalize temperatures of the cavity walls. As an example, Figure 32.52 shows two practical blackbodies. One is a solid-state blackbody having...
thermoelectric elements (heat pumps) that provide either heating or cooling to the cavity body. The embedded temperature sensors are connected to the control circuit (not shown). The function of the multiple temperature sensors is to monitor thermal distribution over the length of the cavity. The inner shape of the cavity is partly conical to increase the number of reflections, and the entire surface is treated to provide it with as high emissivity as possible, typically over 0.9. This type of a blackbody has a relatively wide aperture that potentially can act as an entry for undesirable ambient air. The air can disturb the thermal uniformity inside the cavity, resulting in excessively high uncertainty of the radiated flux. To reduce this problem, the cavity is filled with dry air or nitrogen, which is continuously pumped in through the gas ducts. Before entering the cavity, the gas passes through the narrow channels inside the cavity and acquires the temperature of the blackbody.

Another example is an immersed blackbody. The cavity is fabricated of copper or aluminum and has relatively thin walls (a few millimeters). The entire cavity body is immersed into a stirred liquid bath, the temperature of which is precisely controlled by heating/cooling devices. The liquid assures uniform temperature distribution around the cavity with a typical thermal instability on the order of \( \pm 0.02^\circ C \). The inner surface of the cavity is coated with high-emissivity paint. The aperture of the cavity is relatively small. The ratio of the inner surface of the cavity to the aperture area should be at least 100, and preferably close to 1000.

**Detectors for Thermal Radiation**

**Classification**

Generally speaking, there are two types of sensors (detectors) known for their capabilities to respond to thermal radiation within the spectral range from the near-infrared to far-infrared; that is, from approximately 0.8 \( \mu m \) to 40 \( \mu m \). The first type is quantum detectors; and the second type is thermal detectors. The latter, in turn, can be subdivided into passive (PIR) and active (AFIR) detectors.

**Quantum Detectors**

Quantum detectors (photovoltaic and photoconductive devices) relay on the interaction of individual photons with a crystalline lattice of semiconductor materials. Their operations are based on the photo-effect that was discovered by Einstein, and brought him the Nobel Prize. In 1905, he made a remarkable assumption about the nature of light: that at least under certain circumstances, its energy was concentrated into localized bundles, later named photons. The energy of a single photon is given by:

\[
E = h\nu,
\]

where \( \nu = \) frequency of light

\[
h = 6.63 \times 10^{-34} \text{ J s} \text{ (or } 4.13 \times 10^{-15} \text{ eV s}) = \text{Planck's constant, derived on the basis of the wave theory of light}
\]

When a photon strikes the surface of a conductor, it can result in the generation of a free electron.

The periodic lattice of crystalline materials establishes allowed energy bands for electrons that exist within that solid. The energy of any electron within the pure material must be confined to one of these energy bands, which can be separated by gaps or ranges of forbidden energies.

In isolators and semiconductors, the electron must first cross the energy bandgap in order to reach the conduction band and the conductivity is therefore many orders of magnitude lower. For isolators, the bandgap is usually 5 eV or more; whereas, for semiconductors, the gap is considerably less.

When a photon of frequency \( \nu \), strikes a semiconductive crystal, its energy will be high enough to separate the electron from its site in the valence band and push it through the bandgap into a conduction band at a higher energy level. In that band, the electron is free to serve as a current carrier. The deficiency of an electron in the valence band creates a hole that also serves as a current carrier. This is manifested...
in the reduction of specific resistivity of the material. The energy gap serves as a photon energy threshold, below which the material is not light sensitive.

For measurements of objects emanating photons in the range of 2 eV or greater, quantum detectors having room temperature are generally used. For the smaller energies (longer wavelengths), narrower bandgap semiconductors are required. However, even if a quantum detector has a sufficiently small energy gap, at room temperature, its own intrinsic noise is much greater than a photoconductive signal. Noise level is temperature dependent; therefore, when detecting long-wavelength photons, a signal-to-noise ratio can become so small that accurate measurement becomes impossible. This is the reason why, for the operation in the near- and far-infrared spectral ranges, a detector not only should have a sufficiently narrow energy gap, but its temperature must be lowered to the level where intrinsic noise is reduced to an acceptable level. Depending on the required sensitivity and operating wavelength, the following crystals are typically used for the cryogenically cooled sensors (Figure 32.53): lead sulfide (PbS), indium arsenide (InAs), germanium (Ge), lead selenide (PbSe), and mercury-cadmium-telluride (HgCdTe).

The sensor cooling allows responses to longer wavelengths and increases sensitivity. However, response speeds of PbS and PbSe become slower with cooling. Methods of cooling include dewar cooling using dry ice, liquid nitrogen, liquid helium, or thermoelectric coolers operating on the Peltier effect.

**Thermal Detectors**

Another class of infrared radiation detectors is called thermal detectors. Contrary to quantum detectors that respond to individual photons, thermal detectors respond to heat resulting from absorption of thermal radiation by the surface of a sensing element. The heat raises the temperature of the surface, and this temperature increase becomes a measure of the net thermal radiation.

The Stefan–Boltzmann law (Equation 32.95) specifies radiant power (flux) which would emanate from a surface of temperature, \( T \), toward an infinitely cold space (at absolute zero). When thermal radiation is detected by a thermal sensor, the opposite radiation from the sensor toward the object must also be taken in account. A thermal sensor is capable of responding only to a net thermal flux, i.e., flux from the object minus flux from itself. The surface of the sensor that faces the object has emissivity \( \varepsilon \), (and,
subsequently reflectivity \( r = 1 - \varepsilon_s \). Because the sensor is only partly absorptive, the entire flux, \( \Phi_{bo} \), is not absorbed and utilized. A part of it, \( \Phi_{ba} \), is absorbed by the sensor, while another part, \( \Phi_{br} \), is reflected (Figure 32.54) back toward the object (here, it is assumed that there is 100% coupling between the object and the sensor, and there are no other objects in the sensor’s field of view). The reflected flux is proportional to the sensor’s coefficient of reflectivity:

\[
\Phi_{br} = -\varepsilon_s \Phi_{bo} = -A\varepsilon_s (1 - \varepsilon_s) \sigma T^4 \tag{32.104}
\]

A negative sign indicates an opposite direction with respect to flux \( \Phi_{bo} \). As a result, the net flux originated from the object is:

\[
\Phi_b = \Phi_{bo} + \Phi_{br} = A\varepsilon_s \sigma T^4 \tag{32.105}
\]

Depending on its temperature \( T_s \), the sensor’s surface radiates its own net thermal flux toward the object in a similar way:

\[
\Phi_s = -A\varepsilon\sigma T_s^4 \tag{32.106}
\]

Two fluxes propagate in the opposite directions and are combined into a final net flux existing between two surfaces:

\[
\Phi = \Phi_b + \Phi_s = A\varepsilon\varepsilon_s \sigma \left( T^4 - T_s^4 \right) \tag{32.107}
\]

This is a mathematical model of a net thermal flux that is converted by a thermal sensor into the output signal. It establishes a connection between thermal power, \( \Phi \), absorbed by the sensor, and the absolute temperatures of the object and the sensor. It should be noted that since the net radiation exists between the two bodies, the spectral density will have the maximum not described by Equation 32.92; but depending on the temperature gradient, it will be somewhat shifted toward the shorter wavelengths.

Dynamically, the temperature \( T \) of a thermal element in a sensor, in general terms, can be described by the first-order differential equation:

\[
cm \frac{dT}{dt} = P - P_L - \Phi \tag{32.108}
\]
where \( P \) is the power supplied to the element from a power supply or an excitation circuit (only in AFIR sensors; see below); \( P_L \) is a nonradiative thermal loss attributed to thermal conduction and convection; \( m \) and \( c \) are the sensor’s mass and specific heat, respectively; and \( \Phi = \Phi_h + \Phi_c \) is the net radiative thermal flux. We select a positive sign for power \( P \) when it is directed toward the element.

In the PIR detector (thermopiles, pyroelectric, and bolometers), no external power is supplied (\( P = 0 \)); hence, the speed response depends only on the sensor’s thermal capacity and heat loss, and is a first-order function that is characterized by a thermal time constant \( \tau_T \).

Thermopile Sensors.
Thermopiles belong to a class of PIR detectors. Their operating principle is the same as that of thermocouples. In effect, a thermopile can be defined as serially connected thermocouples. Originally, it was invented by Joule to increase the output signal of a thermoelectric sensor; he connected several thermocouples in series and thermally joined together their hot junctions. Presently, thermopiles have a different configuration. Their prime application is detection of thermal radiation.

A cut-out view of a thermopile sensor is shown in Figure 32.55. The sensor consists of a base having a relatively large thermal mass, which is the place where the “cold” junctions are positioned. The base can be thermally coupled with a reference temperature sensor or attached to a thermostat having a known temperature. The base supports a thin membrane whose thermal capacity and thermal conductivity are small. The membrane is the surface where the “hot” junctions are positioned.

The best performance of a thermopile is characterized by high sensitivity and low noise, which can be achieved by the junction materials having high thermoelectric coefficient, low thermal conductivity, and low volume resistivity. Besides, the junction pairs should have thermoelectric coefficients of opposite signs. This dictates the selection of materials. Unfortunately, most of metals having low resistivity (i.e., gold, copper, silver) have only very poor thermoelectric coefficients. The higher resistivity metals (especially bismuth and antimony) possess high thermoelectric coefficients and they are the prime selection for designing thermopiles. By doping these materials with Se and Te, the thermoelectric coefficient has been improved up to 230 \( \mu \text{V K}^{-1} \) [1].

Methods of construction of metal junction thermopiles can differ to some extent, but all incorporate vacuum deposition techniques and evaporation masks to apply the thermoelectric materials, such as bismuth and antimony on thin substrates (membranes). The number of junctions varies from 20 to several hundreds. The “hot” junctions are often blackened (e.g., with goldblack or organic paint) to improve their absorptivity of the infrared radiation. A thermopile is a dc device with an output voltage that follows its “hot” junction temperature quite well. It can be modeled as a thermal flux-controlled
voltage source that is connected in series with a fixed resistor. The output voltage $V_s$ is nearly proportional to the incident radiation.

An efficient thermopile sensor can be designed using a semiconductor rather than double-metal junctions [2]. The thermoelectric coefficients for crystalline and polycrystalline silicon are very large and the volume resistivity is relatively low. The advantage of using silicon is in the possibility of employing standard IC processes. The resistivity and the thermoelectric coefficients can be adjusted by the doping concentration. However, the resistivity increases much faster, and the doping concentration must be carefully optimized for the high sensitivity–low noise ratios. Semiconductor thermopile sensors are produced with a micromachining technology by EG&G Heimann Optoelectronics GmbH (Wiesbaden, Germany) and Honeywell (Minneapolis, MN).

Pyroelectrics.

Pyroelectric sensors (see Chapter 6) belong to a class of PIR detectors. A typical pyroelectric sensor is housed in a metal TO-5 or TO-39 for better shielding and is protected from the environment by a silicon or any other appropriate window. The inner space of the can is often filled with dry air or nitrogen. Usually, two sensing elements are oppositely, serially or in parallel, connected for better compensation of rapid thermal changes and mechanical stresses resulting from acoustic noise and vibrations [3].

Bolometers.

Bolometers are miniature RTDs or thermistors, which are mainly used for measuring rms values of electromagnetic signals over a very broad spectral range from microwaves to near-infrared. An external bias power is applied to convert resistance changes to voltage changes. For the infrared thermometers, the bolometers are often fabricated in the form of thin films having relatively large area. The operating principle of a bolometer is based on a fundamental relationship between the absorbed electromagnetic signal and dissipated power [3].

The sensitivity of the bolometer to the incoming electromagnetic radiation can be defined as [4]:

$$
\beta = \frac{1}{2} \varepsilon \alpha_o \sqrt{\frac{R_e Z_t \Delta T}{(1 + \alpha_o \Delta T)^2 + \omega^2 \tau^2}}
$$

(32.109)

where $\alpha = (dR/dT)/R = \text{TCR}$ (temperature coefficient of resistance) of the bolometer

- $\varepsilon$ = Surface emissivity
- $Z_t$ = Bolometer thermal resistance, which depends on its design and the supporting structure
- $\tau$ = Thermal time constant, which depends on $Z_t$ and the bolometer’s thermal capacity
- $\omega$ = Angular frequency
- $\Delta T$ = Bolometer’s temperature increase

Bolometers are relatively slow sensors and are used primarily when no fast response is required. For thermal imaging, bolometers are available as two-dimensional arrays of about 80,000 sensors [5].

Active Far-Infrared Sensors.

In the active far-infrared (AFIR) sensor, a process of measuring thermal radiation flux is different from previously described passive (PIR) detectors. Contrary to a PIR sensing element — the temperature of which depends on both the ambient and the object’s temperatures — the AFIR sensor’s surface is actively controlled by a special circuit to have a defined temperature $T_s$ that, in most applications, is maintained constant during an entire measurement process [6]. To control the sensor’s surface temperature, electric power $P$ is provided by a control (or excitation) circuit (Figure 32.56). To regulate $T_s$, the circuit measures the element’s surface temperature and compares it with an internal reference.
Obviously, the incoming power maintains $T_s$ higher than ambient, practically by just several tenths of a degree Celsius. Since the element’s temperature is above ambient, the sensing element loses thermal energy toward its surroundings, rather than passively absorbing it, as in a PIR detector. Part of the heat loss is in the form of a thermal conduction; part is a thermal convection; and the other part is thermal radiation. The third part is the one that must be measured. Of course, the radiative flux is governed by the fundamental Stefan–Boltzmann law for two surfaces (Equation 32.99).

Some of the radiation power goes out of the element to the sensor’s housing, while the other is coming from the object (or goes to the object). What is essential is that the net thermal flow (conductive + convective + radiative) must always come out of the sensor; that is, it must have a negative sign.

In the AFIR element, after a warm-up period, the control circuit forces the element’s surface temperature $T_s$ to stay constant; thus,

$$\frac{dT_s}{dt} = 0 \quad (32.110)$$

and Equation 32.108 becomes algebraic:

$$P = P_L + \Phi \quad (32.111)$$

It follows from the above that, under idealized conditions, its response does not depend on thermal mass and is not a function of time, meaning that practical AFIR sensors are quite fast. If the control circuit is highly efficient, since $P_L$ is constant at given ambient conditions, the electronically supplied power $P$ should track changes in the radiated flux $\Phi$ with high fidelity. Nonradiative loss $P_L$ is a function of ambient temperature $T_a$ and a loss factor $\alpha_s$:

$$P_L = \alpha_s \left(T_s - T_a\right) \quad (32.112)$$

To generate heat in the AFIR sensor, it may be provided with a heating element having electrical resistance $R$. During the operation, electric power dissipated by the heating element is a function of voltage $V$ across that resistance

$$P = \frac{V^2}{R} \quad (32.113)$$

FIGURE 32.56 (A) AFIR element radiates thermal flux $\Phi_b$ toward its housing and absorbs flux $\Phi_b$ from the object. (B) Timing diagrams for radiative flux, surface temperature, and supplied power.
Substituting Equations 32.107, 32.112, and 32.113 into Equation 32.111, and assuming that $T = T_b$ and $T_s > T_a$ after simple manipulations, the object’s temperature can be presented as function of voltage $V$ across the heating element:

$$
T_b = \frac{1}{4} T_s^4 - \frac{1}{A \sigma \varepsilon_b} \left( \frac{V^2}{R} - \alpha \Delta T \right)
$$

(32.114)

where $\Delta T$ is the constant temperature increase above ambient. Coefficient $\alpha$ has a meaning of thermal conductivity from the AFIR detector to the environment (housing).

One way to fabricate an AFIR element is to use a discrete thermistor having a relatively large surface area (3 mm² to 10 mm²) and operating in a self-heating mode. Electric current passing through the thermistor results in a self-heating effect that elevates the thermistor’s temperature above ambient. In effect, the thermistor operates as both the heater and a temperature sensor.

Contrary to a PIR detector, an AFIR sensor is active and can generate a signal only when it works in orchestra with a control circuit. A control circuit must include the following essential components: a reference to preset a controlled temperature, an error amplifier, and a driver stage for the heater. In addition, it may include an RC network for correcting a loop response function and for stabilizing its operation; otherwise, an entire system could be prone to oscillations [7].

It can be noted that an AFIR sensor, along with its control circuit, is a direct converter of thermal radiative power into electric voltage and a quite efficient one. Its typical responsivity is in the range of 3000 V W⁻¹, which is much higher as compared with a thermopile, whose typical responsivity is in the range of 100 V W⁻¹. More detailed description of an AFIR sensor can be found in [3, 6].

**Pyrometers**

**Disappearing Filament Pyrometer**

Additional names for the disappearing filament pyrometer include: *optical pyrometer* and *monochromatic-brightness radiation thermometer*. This type of pyrometer is considered the most accurate radiation thermometer for temperatures over 700°C. This limitation is a result of human-eye sensitivity within a specific wavelength. The operating principle of this thermometer is based on Planck’s law (Equation 32.90 and Figure 32.48) which states that intensity and color of the surface changes with temperature. The idea behind the design is to balance a radiation from an object having a known temperature against unknown temperature from a target. The pyrometer has a lens through which the operator views the target (Figure 32.57A). An image of a tungsten filament is superimposed on the image of the target. The filament

![Disappearing filament optical pyrometer](image-url)

**FIGURE 32.57** Disappearing filament optical pyrometer: (A): Manual, and (B): automatic versions.
is warmed up by electric current to glow. During the calibration, the relationship between the current and the filament temperature was established by measuring brightness of a blackbody of known temperature. The operator views the target through the eyepiece and manually adjusts the heating current to the level when an image of the glowing filament visible in the foreground disappears — that is, when both the target and the filament have the same brightness and color. A color component complicates the measurement somewhat; so to remove this difficulty, a narrow-band red filter (\(\lambda_f = 0.65\) \(\mu\)m) is inserted in front of an eyepiece. Therefore, the operator has to balance only the brightness of an image visible in red color. Another advantage of the filter is that the emissivity \(\varepsilon_{bf}\) of the target needs to be known only at \(\lambda_f\). The error in temperature measurement is given by [8]:

\[
\frac{dT_b}{T_b} = -\frac{\lambda_f T_b}{C_2} \frac{d\varepsilon_{bf}}{\varepsilon_{bf}}
\]  

(32.115)

Thus, for a target at \(T_b = 1000\) K, a 10% uncertainty in knowing emissivity of the target at the filter's wavelength results in only ±0.45% (±4.5 K) uncertainty in measured temperature.

The instrument can be further improved by removing an operator from the measurement loop. Figure 32.57B shows an automatic version of the pyrometer where a rotating mirror tilted by 45° has a removed sector that allows the light from a target to pass through to the photosensor. Such a mirror serves as a chopper, which alternately sends light to a photosensor, either from a target or from the filament. The microprocessor (\(\mu\)P) adjusts current through the filament to bring the optical contrast to zero. The optocoupler provides a synchronization between the chopper and the microprocessor.

**Two-color Pyrometer**

Since emissivities of many materials are not known, measurement of a surface temperature can become impractical, unless the emissivity is excluded from the calculation. This can be accomplished by use of a ratiometric technique: the so called “two-color radiation thermometer” or *ratio thermometer*. In such a thermometer, the radiation is detected at two separate wavelengths \(\lambda_x\) and \(\lambda_y\) for which emissivities of the surface can be considered nearly the same. The coefficients of transmission of the optical system at each wavelength respectively are \(\gamma_x\) and \(\gamma_y\), then the ratio of two equations (2) calculated for two wavelengths is:

\[
\phi = \frac{W_x}{W_y} = \frac{\gamma_x \varepsilon(\lambda_x) \frac{C_x}{\pi} \varepsilon(\lambda_x) \lambda_x^2 e^{-\frac{C_x}{\lambda_x T}}}{\gamma_y \varepsilon(\lambda_y) \frac{C_y}{\pi} \varepsilon(\lambda_y) \lambda_y^2 e^{-\frac{C_y}{\lambda_y T}}}
\]  

(32.116)

Because the emissivities \(\varepsilon(\lambda_x) = \varepsilon(\lambda_y)\), after manipulations, Equation 32.116 can be rewritten for the displayed temperature \(T_c\), where \(\phi\) represents the ratio of the thermal radiation sensor outputs at two wavelengths:

\[
T_c = C_2 \left[ \frac{1}{\lambda_y} - \frac{1}{\lambda_x} \right] \left( \ln \phi \frac{\gamma_x \lambda_x^2}{\gamma_y \lambda_y^2} \right)^{-1}
\]  

(32.117)

It is seen that the equation for calculating temperature does not depend on the emissivity of the surface. Equation 32.117 is the basis for calculating temperature by taking the ratio of the sensor outputs at two different wavelengths. Figure 32.58 shows a block diagram of an IR thermometer where an optical modulator is designed in the form of a disk with two filters.
IR Thermometers

Operating Principle

Infrared (IR) Thermometer with PIR Sensors.

The operating principle of a noncontact infrared (IR) thermometer is based on the fundamental Stefan-Boltzmann law (Equation 32.118). For the purposes of calculating the object’s temperature, when using the PIR sensor (thermopile, bolometer, or pyroelectric), the equation can be manipulated as:

$$T_c = \sqrt[4]{T_0^4 + \frac{\Phi}{\sigma \alpha \varepsilon \varepsilon}}$$

where $T_c$ is the calculated object’s temperature in kelvin. Hence, to calculate the temperature of an object, one should first determine the magnitude of net thermal radiation flux $\Phi$ and the sensor’s surface temperature $T_s$. The other parts of Equation 32.118 are considered as constants and must be determined during the calibration of the instrument from a blackbody. Emissivity of the object $\varepsilon$ also must be known before the calculation. In practice, it is sometimes difficult to determine the exact temperature $T_s$ of the sensor’s surface, due to changing ambient conditions, drifts, handling of the instrument, etc. In such cases, the IR thermometer can be supplied with a reference target. Then, the calculation can still be done with the use of Equation 32.118; however, the value of $\Phi$ will have a meaning of a flux differential between the object and the reference target, and the value of $T_s$ will represent the reference target temperature.

IR Thermometer with AFIR Sensor.

The object’s temperature can be calculated from Equation 32.118; but first the sensing element surface temperature should be determined by measuring the temperature of the sensor’s housing: $T_s = T_a + \Delta T$, where $\Delta T$ is the constant. In addition, the value of $V$ must be measured. The AFIR sensor allows for continuous monitoring of temperature in a manner similar to thermopile sensors. Its prime advantage is simplicity and low cost.

Continuous Monitoring of Temperature

Depending on the type of thermal radiation sensor employed, a non-contact infrared thermometer for continuous monitoring can incorporate different components. Thus, if a sensor with a dc response is
used, the circuit might look like the one shown in Figure 32.59. It has the following essential components: the optical system (the lens), the IR sensor (a thermopile in this example), the reference (ambient) sensor, and a conventional data acquisition circuit. The dc-type sensors are the thermopiles, bolometers, and AFIR. When the AFIR sensor is used, it should be supplied with an additional control circuit, as described above.

In the case when an ac-type of IR sensor is used (pyroelectric), the thermometer needs a chopper that breaks the IR radiation into series pulses, usually with a 50% duty cycle (Figure 32.60). The output of an amplifier is an alternate signal that has a magnitude dependent on both the chopping rate and the net IR radiation. The rotation of the chopper is synchronized with the data processing by the microprocessor by means of an optocoupler (LED and photodetector). It should be noted that the chopper not only converts the IR flux into an ac signal, but it also serves as a reference target, as described above. Use of a reference target can significantly improve IR thermometer accuracy; thus, the chopper is often employed, even with the dc-type sensors, although it is not essential for operation. Naturally, the chopper’s surface emissivity will be high and known.

**Intermittent Monitoring of Temperature**

Obviously, any infrared thermometer capable of continuous monitoring of temperature can be made operational in the intermittent mode. In other words, the continuous temperature can be processed to extract a single value of temperature that might be of interest to the user. For example, it may be a maximum, a minimum, or an averaged over time temperature; yet it is possible to design a low-cost IR thermometer that takes only a “snapshot” of the temperature at any specific moment. Such a thermometer
can be designed with a pyroelectric sensor that produces electric charge virtually instantaneously upon receiving the IR radiation. Figure 32.61A shows a block diagram of such a thermometer. A mechanical or electromechanical shutter is positioned in front of the pyroelectric sensor. The shutter surface serves as a reference target. When the shutter is closed, the sensor produces no output. Immediately upon shutter actuation, the pyroelectric current flows from the sensor into an amplifier that contains a charge-to-voltage converter. The sensor’s current response has a shape close to the exponential function (Figure 32.61B). The magnitude of the spike is nearly proportional to the IR flux at the moment of the shutter opening. The pyroelectric thermometer is widely used for medical purposes and is dubbed the “instant thermometer.”

Response Speed

All infrared thermometers are relatively fast; their typical response time is on the order of a second. Along with the non-contact way of taking temperature, this makes these devices very convenient whenever fast tracking of temperature is essential. However, an IR thermometer, while being very fast, still can require a relatively long warm-up time, and may not be accurate whenever it is moved from one environment to another without having enough time to adapt itself to new ambient temperature. The reason for this is that the reference and IR sensors (or the IR sensor and the shutter or chopper) must be in thermal equilibrium with one another; otherwise, the calculated temperature is erroneous.

Components of IR Thermometers

Optical Choppers and Shutters

The shutters or choppers must possess the following properties: (1) they should have high surface emissivity that does not change with time; (2) the opening and closing speed must be high; (3) the thermal conductivity between the front and back sides of the blade should be as small as possible; (4) the blade should be in good thermal contact with the reference sensor; and (5) while operating, the blade should not wear off or produce microscopic particles of dust that could contaminate the optical components of the IR thermometer.

For operation in the visible and near-infrared portions of the spectrum, when measured temperatures are over 800 K, the shutter can be fabricated as a solid-state device without the use of moving components.
(e.g., employing liquid crystals). However, for longer wavelengths, only the mechanical blades are useful. Special attention should be paid with regard to the prevention of reflection by the shutter or chopper of any spurious thermal radiation that originates from within the IR thermometer housing.

Filters and Lenses

The IR filters and lenses serve two purposes: they selectively pass specific wavelengths to the sensing components, and they protect the interior of the instrument from undesirable contamination by outside pollutants. In addition, lenses — due to their refractive properties — divert light rays into specific direction [3]. In IR thermometry, the selection of filters and lenses is limited to a relatively short list. Table 32.18 lists some materials that are transparent in the infrared range. Note that most of these materials have a relatively high refractive index, which means that they have high surface reflectivity loss. For example, silicon (the cheapest material for the IR windows) reflects over 46% of incoming radiation which along with the absorptive loss, amounts to an even higher value of combined loss. To a certain degree, this problem can be solved by applying special antireflective (AR) coatings on both surfaces of the window or lens. These coatings are geared to specific wavelengths; thus, for a broad bandwidth, a multilayer coating may need to be deposited by a sputtering process.

Another problem with IR refractive materials is the relatively high absorption of light. This becomes a serious limitation for the lenses, as they need to be produced with appreciable thickness. The solution is to select materials with low absorption in the spectral range of interest. Examples are zinc selenide (ZnSe) and AMTIR. Another solution is the use of polyethylene Fresnel lenses, which are much thinner and less expensive [3]. Any window or lens that is absorptive will also emanate thermal radiation according to its own temperature. Hence, to minimize this effect on the overall accuracy of an IR thermometer, the refractive devices should be kept at the same temperature as the IR sensor, the shutter (chopper), and the reference sensor.

Waveguides

Waveguides are optical components intended for channeling IR radiation from one point to another. Usually, they are used when an IR sensor cannot be positioned close to the source of thermal radiation, yet must have a wide field of view. These components employ light reflection and are not focusing, even if they are designed with refractive materials. If focusing is required, the waveguides can be combined with lenses and curved or tilted mirrors. A waveguide has relatively wide entry and exit angles. A typical application is in a medical IR thermometer, where the waveguide is inserted into an ear canal (Figure 32.61).
There are three types of waveguides: hollow tubes (barrels), optical fibers, and rods [3, 9, 10]. The latter two are made of IR-transparent materials, such as ZnSe or AMTIR, and use the angle of total internal reflection to propagate light inside in a zigzag pattern (Figure 32.62). The barrels are hollow tubes, polished and gold-plated on the inner surface.

**Error Sources in IR Thermometry**

Any error in detection of either radiated flux ($\Phi$) or reference temperature ($T_r$) will result in inaccuracy in the displayed temperature. According to Equation 32.118, the emissivities of both the sensor ($\varepsilon_s$) and the object ($\varepsilon_o$) must be known for the accurate detection of thermal flux. Emissivity of the sensor usually remains constant and is taken care of during the calibration. However, uncertainty in the value of emissivity of the object can result in significant uncertainty in temperatures measured by non-contact infrared thermometers (Figure 32.63).

---

**FIGURE 32.62** Light inside the barrel (A), rod (B) and fiber-optic (C) propagates on a zigzag path.

**FIGURE 32.63** Error in temperature measurement resulted from uncertainty in the value of object’s emissivity.
Another source of an error is spurious heat sources, which can emanate their thermal radiation either directly into the optical system of an IR thermometer, or by means of reflection from the measured surface [11]. Since no surface is an ideal emitter (absorber), its reflectivity may have significant value. For example, an opaque object with emissivity 0.9 has reflectivity of 0.1 (Equation 32.54); thus, about 10% of the radiation from a hot object in the vicinity of a measured surface is reflected and can greatly disturb the measurement.

Since emissivities of metals are quite small and one never can be sure about their actual values, it is advisable, whenever practical, to coat a portion of a metal surface with a dielectric material, such as metal oxide or organic paint having known emissivity. Alternatively, temperatures should not be taken from a flat surface, but rather from a hole or cavity that inside has a nonmetallic surface.

Another source of error is the thermal instability of the thermal sensing element. For example, in a thermopile or pyroelectric sensor, upon exposure to thermal radiation, the element’s temperature might increase above ambient by just a few millidegrees. Hence, if for some reason, the element’s temperature varies by the same amount, the output signal becomes indistinguishable from that produced by the thermal flux. To minimize these errors, the infrared sensors are encapsulated into metal bodies having high thermal capacity and poor coupling to the environment (high thermal resistance), which helps to stabilize the temperature of the sensor. Another powerful technique is to fabricate the IR sensor in a dual form; that is, with two identical sensing elements. One element is subjected to an IR signal, while the other is shielded from it. The signals from the elements are subtracted, thus canceling the drifts that affect both elements [3].

Some Special Applications

Semiconductor Materials

Temperature measurement of semiconductor material during processing, such as growth of epitaxial films in vacuum chambers, always has been a difficult problem. Various process controls require accurate temperature monitoring, often without physical contact with the substrates. As a rule, heating of a substrate is provided by resistive heaters. The substrates are often loaded into the chambers through various locks and rotated during processing. Therefore, it is very difficult to attach a contact sensor, such as a thermocouple, to the wafer. And, even if one does so, the thermal gradient between the sensor and the substrate may be so large that one should never trust the result. The attractive alternative is optical pyrometry; however, this presents another set of difficulties. The major problem is that semiconductors are substantially transparent in the spectral region where thermal radiation would be emanated. In other words, the emissivity of a semiconductor is negligibly small and the amount of thermal radiation from a semiconductor is also not only small, but due to wafer transparency, the radiation from the underlying devices (e.g., heater) will go through to the IR thermometer.

One relatively simple method is to coat a small portion of the semiconductor with a material having high emissivity in the IR spectral range. Then, the thermal radiation can be measured from that patch. An example of such a material is nichrome (see Table 32.17).

An attractive method of temperature monitoring, when no emissive patch can be deposited, is the use of temperature dependence of bandgaps of common semiconductors. The bandgap is determined from the threshold wavelength at which the radiation from the heaters behind the substrate is transmitted through the substrate [12]. Another method is based on the temperature dependence of diffuse reflection of a semiconductor. In effect, this method is similar to the former; however, it relies on reflection, rather than on transmission of the semiconductor. An external lamp is used for the measurement of a threshold wavelength from a front polished and backside textured substrate [13]. The temperature measurement arrangement is shown in Figure 32.64 where the diffused light is detected by cryogenically cooled quantum detector. The monochromator has resolution of 3 nm and scans through the threshold area at a rate of 100 nm/s.
Medical Applications

Medical infrared thermometry has two distinct types of measurements: body temperature measurement and skin surface temperature measurement. Skin temperature measurements have specific applications in determining surface temperature of a human body. That temperature greatly depends on both the skin blood perfusion and environmental conditions. Therefore, skin temperature cannot be independently correlated with the internal body temperature.

Now, it is customary to measure the internal body temperature by placing the probe of an IR thermometer into the ear canal aiming it at a tympanic membrane [14]. The tympanic membrane has temperature close to that of blood. As a rule, the probe is designed with a gold-plated waveguide (Figure 32.61) which is protected either by a semiconductor or polymer window. Because a medical IR thermometer is used in direct contact with patient tissues, it is imperative to protect the probe from becoming a carrier of soiling compounds and a transmitter of infection from one patient to another (cross-contamination) or even from re-infecting the same patient (recontamination). Thus, a probe of a medical IR thermometer is protected by a special probe cover made of a polymer film (polyethylene, polypropylene, etc.) which is transparent in the spectrum range of thermal radiation. In effect, the probe cover becomes a part of the optical system. This demands that covers be produced with very tight tolerances so that they will not significantly affect transmission of IR signal.

32.7 Pyroelectric Thermometers

Jacob Fraden

Pyroelectric Effect

The pyroelectric materials are crystalline substances capable of generating an electric charge in response to heat flow [1]. The pyroelectric effect is very closely related to the piezoelectric effect. The materials belong to a class of ferroelectrics. The name was given in association with ferromagnetics and is rather misleading because most such materials have nothing to do with iron.

A crystal is considered to be pyroelectric if it exhibits a spontaneous temperature-dependent polarization. Of the 32 crystal classes, 21 are noncentrosymmetric and 10 of these exhibit pyroelectric properties. Besides pyroelectric properties, all these materials exhibit some degree of piezoelectric properties as well — they generate an electric charge in response to mechanical stress.

Pyroelectricity was observed for the first time in tourmaline crystals in the 18th century (some claim that the Greeks noticed it 23 centuries ago). Later, in the 19th century, Rochelle salt was used to make pyroelectric sensors. A large variety of materials became available after 1915: KDP (KH2PO4), ADP (NH4H2PO4), BaTiO3, and a composite of PbTiO3 and PbZrO3 known as PZT. Presently, more than 1000 materials with reversible polarization are known. They are called ferroelectric crystals. Most important among them are triglycine sulfate (TGS) and lithium tantalate (LiTaO3).

A pyroelectric material can be considered a composition of a large number of minute crystallites, where each behaves as a small electric dipole. All these dipoles are randomly oriented, however, along a preferred direction. Above a certain temperature, known as the Curie point, the crystallites have no dipole moment.

When temperature of a pyroelectric material changes, the material becomes polarized. In other words, an electric charge appears on its surface. It should be clearly understood that the polarization occurs not as a function of temperature, but only as function of a change in temperature of the material. There are several mechanisms by which changes in temperature will result in pyroelectricity. Temperature changes can cause shortening or elongation of individual dipoles. It can also affect the randomness of the dipole orientations due to thermal agitation. These phenomena are called primary pyroelectricity. There is also secondary pyroelectricity, which, in a simplified way, can be described as a result of the piezoelectric effect; that is, a development of strain in the material due to thermal expansion.

The dipole moment, \( M \), of the bulk pyroelectric sensor is:

\[
M = \mu A h
\]  

(32.119)
where \( m \) = Dipole moment per unit volume
\( A \) = Sensor’s area
\( h \) = Thickness

The charge, \( Q_a \), which can be picked up by the electrodes, develops the dipole moment across the material:

\[
M = M_0 = Q_a h
\]  
(32.120)

\( M \) must be equal to \( M_0 \), so that:

\[
Q_a = \mu A
\]  
(32.121)

As the temperature varies, the dipole moment also changes, resulting in an induced charge.

Thermal absorption can be related to a dipole change, so that \( \mu \) must be considered a function of both temperature, \( T_a \), and an incremental thermal energy, \( \Delta W_a \) absorbed by the material:

\[
\Delta Q_a = A\mu\left(T_a,\Delta W_a\right)
\]  
(32.122)

The above equation shows the magnitude of electric charge resulting from absorption of thermal energy. To pick up the charge, the pyroelectric materials are fabricated in the shapes of a flat capacitor with two electrodes on opposite sides and the pyroelectric material serving as a dielectric.

**Pyroelectric Materials**

To select the most appropriate pyroelectric material, energy conversion efficiency should be considered. It is, indeed, the function of the pyroelectric sensor to convert thermal energy into electrical. “How effective is the sensor?” — is a key question in the design practice. A measure of efficiency is: \( k_p^2 \) which is called the pyroelectric coupling coefficient [2, 3]. It shows the factor by which the pyroelectric efficiency is lower than the Carnot limiting value \( \Delta T/T_a \). Numerical values for \( k_p^2 \) are shown in Table 32.19.

Table 32.19 shows that triglycine sulfate (TGS) crystals are the most efficient pyroelectric converters. However, for a long time they were quite impractical for use in sensors because of a low Curie temperature. If the sensor’s temperature is elevated above that level, it permanently loses its polarization. In fact, TGS sensors proved to be unstable even below the Curie temperature, with the signal being lost quite spontaneously [4]. It was discovered that doping of TGS crystals with L-alanine (LATGS process patented by

*Note: The above figures may vary depending on manufacturing technologies. From Reference [2].
Philips) during its growth stabilizes the material below the Curie temperature. The Curie temperature was raised to 60°C, which allows its use at the upper operating temperature of 55°C, which is sufficient for many applications.

Other materials, such as lithium tantalate and pyroelectric ceramics, are also used to produce pyroelectric sensors. Polymer films (KYNAR from AMP Inc.) have become increasingly popular for a variety of applications. During recent years, deposition of pyroelectric thin films has been intensively researched. Especially promising is the use of lead titanate (PbTiO₃), which is a ferroelectric ceramic having both a high pyroelectric coefficient and a high Curie temperature of about 490°C. This material can be easily deposited on silicon substrates by the so called sol-gel spin casting deposition method [5].

In 1969, Kawai discovered strong piezoelectricity in the plastic materials, polyvinyl fluoride (PVF) and polyvinylidene fluoride (PVDF) [6]. These materials also possess substantial pyroelectric properties. PVDF is a semicrystalline polymer with an approximate degree of crystallinity of 50% [7]. Like other semicrystalline polymers, PVDF consists of a lamellar structure mixed with amorphous regions. The chemical structure contains the repeat unit of doubly fluorinated ethene CF₂-CH₂:

\[
\begin{array}{cccc}
  & H & F \\
\_ & C & C \\
  & H & F \\
\end{array}
\]

The molecular weight of PVDF is about 10⁶, which corresponds to about 2000 repeat units. The film is quite transparent in the visible and near-IR regions, and is absorptive in the far-infrared portion of the electromagnetic spectrum. The polymer melts at about 170°C. Its density is about 1780 kg m⁻³. PVDF is mechanically durable and flexible. In piezoelectric applications, it is usually drawn, uniaxially or biaxially, to several times its length. Elastic constants, for example, Young modulus, depend on this draw ratio. Thus, if the PVDF film was drawn at 140°C to the ratio of 4:1, the modulus value is 2.1 GPa; while for the draw ratio of 6.8:1, it was 4.1 GPa. Resistivity of the film also depends on the stretch ratio. For example, at low stretch, it is about 6.3 × 10¹⁵ Ω cm, while for the stretch ratio 7:1 it is 2 × 10¹⁶ Ω cm.

Since silicon does not possess pyroelectric properties, such properties can be added on by depositing crystalline layers of pyroelectric materials. The three most popular materials are zinc oxide (ZnO), aluminum nitride (AlN), and the so-called solid solution system of lead-zirconate-titanium oxides Pb(Zr,Ti)O₃, known as PZT ceramic, which is basically the same material used for fabrication of discrete piezoelectric and pyroelectric sensors. One of the advantages of using zinc oxide is the ease of chemical etching. The zinc oxide thin films are usually deposited on silicon by employing sputtering technology. Note, however, that silicon has a large coefficient of thermal conductivity. That is, its thermal time constant is very small (see below), so the pyroelectric sensors made with silicon substrates possess low sensitivity yet are capable of fast response.

Manufacturing Process

Manufacturing of ceramic PZT elements begins with high-purity metal oxides (lead oxide, zirconium oxide, titanium oxide, etc.) in the form of fine powders having various colors. The powders are milled to a specific fineness, and mixed thoroughly in chemically correct proportions. In a process called "calcining," the mixtures are then exposed to an elevated temperature, allowing the ingredients to react to form a powder, each grain of which has a chemical composition close to the desired final composition. At this stage, however, the grain does not yet have the desired crystalline structure.

The next step is to mix the calcined powder with solid and/or liquid organic binders (intended to burn out during firing) and mechanically form the mixture into a "cake" that closely approximates a shape of the final sensing element. To form the "cakes" of desired shapes, several methods can be used. Among them are pressing (under force of a hydraulic-powered piston), casting (pouring viscous liquid
into molds and allowing to dry), extrusion (pressing the mixture through a die, or a pair of rolls to form thin sheets), and tape casting (pulling viscous liquid onto a smooth moving belt).

After the "cakes" have been formed, they are placed into a kiln and exposed to a very carefully controlled temperature profile. After burning out of organic binders, the material shrinks by about 15%. The "cakes" are heated to a red glow and maintained at that state for some time, which is called the "soak time," during which the final chemical reaction occurs. The crystalline structure is formed when the material is cooled down. Depending on the material, the entire firing may take 24 h.

When the material is cold, contact electrodes are applied to its surface. This can be done by several methods. The most common are: fired-on silver (a silk-screening of silver-glass mixture and refiring), electroless plating (a chemical deposition in a special bath), and sputtering (an exposure to metal vapor in partial vacuum).

Crystallites (crystal cells) in the material can be considered electric dipoles. In some materials, like quartz, these cells are naturally oriented along the crystal axes, thus giving the material sensitivity to stress. In other materials, the dipoles are randomly oriented and the materials need to be "poled" to possess piezoelectric properties. To give a crystalline material pyroelectric properties, several poling techniques can be used. The most popular poling process is thermal poling, which includes the following steps:

1. A crystalline material (ceramic or polymer film) that has randomly oriented dipoles (Figure 32.65A) is warmed to slightly below its Curie temperature. In some cases (for a PVDF film), the material is stressed. High temperature results in stronger agitation of dipoles and permits one to more easily orient them in a desirable direction.
2. The material is placed in strong electric field, \( E \) (Figure 32.65B) where dipoles align along the field lines. The alignment is not total. Many dipoles deviate from the filed direction quite strongly; however, statistically predominant orientation of the dipoles is maintained.
3. The material is cooled down while the electric field across its thickness is maintained.
4. The electric field is removed and the poling process is complete. As long as the poled material is maintained below the Curie temperature, its polarization remains permanent. The dipoles stay "frozen" in the direction that was given to them by the electric field at high temperature (Figure 32.65C). The above method is used to manufacture ceramic and plastic pyroelectric materials.

Another method, called a corona discharge poling, can be used to produce polymer piezo/pyroelectric films. The film is subjected to a corona discharge from an electrode at several million volts per centimeter of film thickness for 40 s to 50 s [8, 9]. Corona polarization is uncomplicated to perform and can be easily applied before electric breakdown occurs, making this process useful at room temperature.

The final operation in preparing the sensing element is shaping and finishing. This includes cutting, machining, and grinding. After the piezo (pyro) element is prepared, it is installed into a sensor's housing, where its electrodes are bonded to electrical terminals and other electronic components.

After poling, the crystal remains permanently polarized; however, it remains electrically charged for a relatively short time. There is a sufficient amount of free carriers that move in the electric field setup.
inside the bulk material and there are plenty of charged ions in the surrounding air. The charge carriers move toward the poled dipoles and neutralize their charges (Figure 32.65C). Hence, after a while, the poled piezoelectric material becomes electrically discharged as long as it remains under steady-state conditions. When temperature changes and thermally induced stress develops, the balanced state is degraded and the pyroelectric material develops an electric charge. If the stress is maintained for a while, the charges again will be neutralized by the internal leakage. Thus, a pyroelectric material is responsive only to a changing temperature rather than to a steady level of it. In other words, a pyroelectric sensor is an ac device, rather than a dc device. Sometimes, it is called a dynamic sensor, which reflects the nature of its response.

**Pyroelectric Sensors**

To make sensors, the pyroelectric materials are used in the form of thin slices or films with electrodes deposited on the opposite sides to collect the thermally induced charges (Figure 32.66). The pyroelectric detector is essentially a capacitor that can be charged by an influx of heat. The detector does not require any external electrical bias (excitation signal). It needs only an appropriate electronic interface circuit to measure the charge. Contrary to thermoelectrics (thermocouples), which produce a steady voltage when two dissimilar metal junctions are held at steady but different temperatures, pyroelectrics generate charge in response to a change in temperature. Since a change in temperature essentially requires propagation of heat, a pyroelectric device is a heat flow detector rather than a heat detector. Figure 32.66 shows a pyroelectric detector (pyro-sensor) connected to a resistor $R_b$ that represents either the internal leakage resistance or a combined input resistance of the interface circuit connected to the sensor. The equivalent electrical circuit of the sensor is shown on the right. It consists of three components: (1) the current source generating a heat induced current, $i$, (remember that a current is a movement of electric charges), (2) the sensor’s capacitance, $C$, and (3) the leakage resistance, $R_b$. Since the leakage resistance is very high and often unpredictable, an additional bias resistor is often connected in parallel with the pyroelectric material. The value of that resistor is much smaller than the leakage resistance, yet its typical value is still on the order of $10^{10}$ Ω (10 GΩ).

The output signal from the pyroelectric sensor can be taken in the form of either charge (current) or voltage, depending on the application. Being a capacitor, the pyroelectric device is discharged when connected to a resistor, $R_b$ (Figure 32.66). Electric current through the resistor and voltage across the resistor represent the heat flow-induced charge. It can be characterized by two pyroelectric coefficients [2]:

\[
P_Q = \frac{dP}{dT} \quad \text{Pyroelectric charge coefficient}
\]

\[
P_V = \frac{dE}{dT} \quad \text{Pyroelectric voltage coefficient}
\]

where $P$ = Spontaneous polarization (which is the other way to say “electric charge”)

- $E$ = Electric field strength
- $T$ = Temperature in K
Both coefficients are related by way of the electric permittivity, \( \varepsilon_r \), and dielectric constant, \( \varepsilon_0 \):

\[
\frac{P_i}{P_e} = \frac{dP}{dE} = \varepsilon_r \varepsilon_0
\]  

(32.124)

The polarization is temperature dependent and, as a result, both pyroelectric coefficients in Equation 32.123 are also functions of temperature.

If a pyroelectric material is exposed to a heat source, its temperature rises by \( \Delta T \), and the corresponding charge and voltage changes can be described by the following equations.

\[
\Delta Q = P_i \Delta T
\]  

(32.125)

\[
\Delta V = P_i \frac{1}{h} \Delta T
\]  

(32.126)

Remembering that the sensor’s capacitance can be defined as:

\[
C = \frac{\Delta Q}{\Delta V} = \varepsilon_r \varepsilon_0 \frac{A}{h}
\]  

(32.127)

then, from Equations 32.124, 32.126, and 32.127, it follows that:

\[
\Delta V = P_i \frac{A}{C} \Delta T = P_i \frac{\varepsilon_r \varepsilon_0}{h} \Delta T
\]  

(32.128)

It is seen that the peak output voltage is proportional to the sensor’s temperature rise and pyroelectric charge coefficient and inversely proportional to its thickness.

Figure 32.67 shows a pyroelectric sensor whose temperature, \( T_o \), is homogeneous over its volume. Being electrically polarized, the dipoles are oriented (poled) in such a manner as to make one side of the material positive and the opposite side negative. However, under steady-state conditions, free charge carriers (electrons and holes) neutralize the polarized charge and the capacitance between the electrodes does not appear to be charged. That is, the sensor generates zero charge. Now, assume that heat is applied to the bottom side of the sensor. Heat can enter the sensor in a form of thermal radiation that is absorbed by the bottom electrode and propagates toward the pyroelectric material via the mechanism of thermal conduction. The bottom electrode can be given a heat-absorbing coating, such as goldblack or organic paint. As a result of heat absorption, the bottom side becomes warmer (the new temperature is \( T_1 \)), which causes the bottom side of the material to expand. The expansion leads to flexing of the sensor, which, in turn, produces stress and a change in dipole orientation. Being piezoelectric, stressed material generates electric charges of opposite polarities across the electrodes. Hence, one can regard secondary pyroelectricity as a sequence of events: a thermal radiation — a heat absorption — a thermally induced stress — an electric charge.

The temperature of the sensor \( T_i \) is a function of time. That function is dependent on the sensing element: its density, specific heat, and thickness. If the input thermal flux has the shape of a step function of time, for the sensor freely mounted in air, the output current can be approximated by an exponential function, so that:

\[
J = J_0 e^{-t/\tau_i}
\]  

(32.129)

where \( J_0 = \) Peak current
Figure 32.68 shows timing diagrams for a pyroelectric sensor when it is exposed to a step function of heat. It is seen that the electric charge reaches its peak value almost instantaneously, and then decays with a thermal time constant, \( \tau_T \). This time constant is a product of the sensor’s thermal capacitance, \( C \), and thermal resistance, \( r \), which defines a thermal loss from the sensing element to its surroundings:

\[
\tau_T = Cr = cAhr
\]  

where \( c \) = Specific heat of the sensing element.

The thermal resistance \( r \) is a function of all thermal losses to the surroundings through convection, conduction, and thermal radiation. For low-frequency applications, it is desirable to use sensors with \( \tau_T \) as large as practical; while for the high-speed applications (e.g., to measure the power of laser pulses), a
thermal time constant should be dramatically reduced. For that purpose, the pyroelectric material can be laminated with a heat sink: a piece of aluminum or copper.

When a heat flow exists inside the pyroelectric crystal, there is an outflow of heat from the opposite side of the crystal, as shown in Figure 32.67. Thermal energy enters the pyroelectric material from side \( a \). Since the other side \( b \) of the sensor faces a cooler environment, part of the thermal energy leaves the sensor and is lost to its surroundings. Because the sides \( a \) and \( b \) face objects of different temperatures (one is the temperature of a target and the other is the temperature of the environment), a continuous heat flow exists through the pyroelectric material. As a result, in Figure 32.68, charge \( Q \) and voltage \( V \) do not completely return to zero, no matter how much time has elapsed. Electric current generated by the pyroelectric sensor has the same shape as the thermal current through its material. An accurate measurement can demonstrate that as long as the heat continues to flow, the pyroelectric sensor will generate a constant voltage \( V_0 \) whose magnitude is proportional to the heat flow.

### Applications

The pyroelectric sensors are useful whenever changing thermal radiation or heat flow need to be measured. Examples are motion detectors for the security systems and light control switches [1], instant medical infrared thermometers, and laser power meters. Depending on the application, a pyroelectric sensor can be used either in current or in voltage mode. The voltage mode (Figure 32.69A) uses a voltage follower with a very high input resistance. Hence, JFET and CMOS input stages are essential. As a rule, in the voltage mode sensor, the follower is incorporated inside the same package along with the element and bias resistor. Advantages of the voltage mode are simplicity and lower noise. The disadvantages are slower speed response due to high capacitance of the sensor (typically on the order of 30 pF) and other influences of the sensor capacitance on the quality of output voltage. The output voltage of the follower is shown in Figure 32.68 (\( V \)). It is seen that it rises slowly with electric time constant \( \tau_e \) and decays with thermal time constant \( \tau_T \).

The current mode uses an electronic circuit having a “virtual ground” as its input (Figure 32.69B). An advantage of this circuit is that the output signal is independent of the sensor’s capacitance and, as a result, is much faster. The signal reaches its peak value relatively fast and decays with thermal time constant \( \tau_T \). The output voltage \( V_0 \) has the same shape of charge \( Q \) in Figure 32.68. The disadvantages of the circuit are higher noise (due to wider bandwidth) and higher cost.

Note that Figure 32.69 shows dual pyroelectric sensors, where two sensing elements are formed on the same crystalline plate by depositing two pairs of electrodes. The electrodes are connected in a serial-opposite manner. If both sensors are exposed to the same magnitude of far-infrared radiation, they will produce nearly identical polarizations and, due to the opposite connection, the voltage applied to the input of the transistor or the current passing through resistor \( R_b \) will be nullified. This feature allows for cancellation of undesirable common-mode input signals in order to improve stability and reduce noise. Signals that arrive only to one of the elements will not be canceled.

32.8 Liquid-In-Glass Thermometers

J.V. Nicholas

The earliest form of thermometer, known as a thermoscope, was a liquid-in-glass thermometer that was open to the atmosphere and thus responded to pressure. By sealing a thermoscope so that it responded only to temperature, the modern form of a liquid-in-glass thermometer resulted. As a temperature sensor, its use dominated temperature measurement for at least 200 years. Liquid-in-glass thermometers had a profound effect on the development of thermometry and, in popular opinion, they are the only "real" thermometers! Liquid-in-glass thermometer sensors were developed in variety to fill nearly every niche in temperature measurement from –190°C to +600°C, including the measurement of temperature differences to a millikelvin. In spite of the fragile nature of glass, the popularity of these thermometers continues because of the chemical inertness of the glass, as well as the self-contained nature of the thermometer.

Measurement sensor designers are unlikely to develop their own liquid-in-glass thermometers, but many will use them to check the performance of a new temperature sensor. The emphasis in this chapter section will therefore be on the use of mercury-in-glass thermometers — the most successful liquid-in-glass thermometer — as calibration references. Mercury-in-glass thermometers provide a stable temperature reference to an accuracy of 0.1°C, provided they are chosen and used with care. The extra requirements to achieve higher accuracy are indicated, but are beyond the scope of this section.

The trend is, however, to move away from mercury-in-glass thermometers for specialized uses (in particular, where the risk from glass or mercury contamination is not acceptable; for example, in the food or aviation industries). Other forms of temperature sensors described in this handbook are be more suitable.

General Description

A common form of mercury-in-glass is a solid-stem glass thermometer illustrated in Figure 32.70. The other major form of liquid-in-glass thermometer is the enclosed scale thermometer, for which the general principles discussed will also apply.

There are four main parts to the liquid-in-glass thermometer:

- The bulb is a thin glass container holding the bulk of the thermometric liquid. The glass must be of suitable type and properly annealed. The thinness is essential for good thermal contact with the medium being measured, but it can result in instabilities due to applied stress or sudden shock.
Some lower-accuracy, general-purpose thermometers are made with a thicker glass bulb to lower the risk of breakage.

- The stem is a glass capillary. Again, a suitable glass is necessary and may differ from that of the bulb. The bore can be gas-filled or vacuous. The volume of the bore must be somewhat smaller than the volume of the bulb for good sensitivity. In addition, the bore must be smooth, with a uniform cross section.
The liquid is usually mercury for best precision, or an organic liquid for lower temperature ranges. The markings are usually etched or printed onto the stem. The markings include the scale, to allow direct reading of the temperature, as well as other important information.

Figure 32.70 illustrates the main parts of a mercury-in-glass thermometer, along with a nomenclature for other features commonly found. Not all of the features will be found on all thermometers.

The operation of liquid-in-glass thermometers is based on the expansion of the liquid with temperature; that is, the liquid acts as a transducer to convert thermal energy into a mechanical form. As the liquid in the bulb becomes hotter, it expands and the liquid is forced up the capillary stem. The temperature of the bulb is indicated by the position of the top of the mercury column with respect to the marked scale. The flattest part of the liquid meniscus is used as the indicator: for mercury, this is the top of the curve; for organic liquids, the bottom.

The thermometers appear to have a simplicity about them, but this is lost when accurate measurements are required. By accuracy, we mean any reading where the temperature needs to be known to within 1°C or better. The chief cause of inaccuracy is that not all of the liquid is at the required temperature due to its necessary presence in the stem. Thus, the thermometer is also sensitive to the stem temperature. The main advantage of a liquid-in-glass thermometer is that it is self-contained; but this means that the thermometer stem has to be seen to read the scale. Even in a well-designed apparatus, a good part of the stem will not be at the temperature of the bulb. For example, with a bulb immersed in boiling water and the entire stem outside, an error of 1°C results from the cooler stem. Correction for this error can be incorporated in the scale of a partial immersion thermometer, or the error can be corrected with a chart of stem corrections.

The next most significant cause of error comes from the glass, a substance with complex mechanical properties. Like mercury, it expands rapidly on heating but does not contract immediately on cooling. This produces a hysteresis which, for a good glass, is about 0.1% of the temperature change. A good, well-annealed thermometer glass will relax back over a period of days. An ordinary glass might never recover its shape. Besides this hysteresis, the glass bulb undergoes a secular contraction over time; that is, the thermometer reading increases with age, but fortunately the effect is slow and calibration checks at the ice point, 0°C, can correct for it.

A bewildering number of types of liquid-in-glass thermometers are available, with many of the variations being designed with different dimensions and temperature ranges to suit specific applications.

For best performance, solid-stem mercury-in-glass thermometers should be restricted to operation over the maximum range –38°C to 250°C. The purchase should be guided by a specification as published by a recognized standards body. Such bodies include the International Standards Organisation (ISO) [1]; the American Society for Testing and Materials (ASTM) [2]; the British Standards Institute (BSI) [3]; or the Institute for Petroleum (IP). Be aware that some type numbers are the same, yet may refer to different thermometers, such as in the IP and ASTM ranges. Make sure the specification body is referred to; for example, an order for a 16C thermometer could result in either an ASTM 10C, the equivalent of an IP 16C, or an IP 61C, the equivalent of ASTM 16C.

One’s choice of thermometer will most probably be a compromise between the best range, scale division, and length for the purpose. If good precision is required, then the thermometer range will be constrained to avoid extremely long and unwieldy thermometers. Table 32.20 gives the specification for precision thermometers based on the compromise as seen by the ASTM [2]. The cost of these thermometers depends on the range and varies from $50 to $180 at 1996 prices. The best precision for the ASTM liquid-in-glass thermometers is around 0.1°C, with the thermometers supplied being accurate to one scale division. Consult the references at the end of this chapter section if higher-resolution thermometers are required. As a rule, choose thermometers subdivided to the accuracy desired, and do not rely on visual interpolation to increase the accuracy. If relying heavily on interpolation, then a better choice of thermometer should be made.

Table 32.20 has thermometers with an ice point either in the main scale or as an auxiliary scale. The ice point is a very convenient way to check on the on-going performance of a thermometer, and without it, more expensive time-consuming procedures may be needed.
### Liquid Expansion

The equation that best describes the expansion of the mercury volume is:

\[
V = V_0 \left(1 + \alpha t + \beta t^2 \right)
\]  
(32.131)

where \(V_0\) = Volume of mercury at 0°C

\[\alpha\] and \[\beta\] = Coefficients of thermal expansion of mercury, with

\[
\alpha = 1.8 \times 10^{-4} \text{°C}^{-1}
\]

\[
\beta = 5 \times 10^{-8} \text{°C}^{-2}
\]

See Table 32.21 for the expansion coefficients of other liquids and their range of use.

Equation 32.131 is the ideal equation for a mercury-in-glass thermometer. In practice, several factors modify the ideal behavior because of the way in which the thermometers are constructed.

Because the glass of a mercury-in-glass thermometer also expands, it is the apparent expansion coefficient due to the differential expansion of the mercury with respect to the glass that is of interest. Glass used in a typical thermometer has a value of \(\alpha = 2 \times 10^{-5} \text{°C}^{-1}\), about 10% that of mercury. Hence, both the glass and the mercury act as temperature transducers and thus justify the description “mercury-in-glass.”

The mercury also serves as the temperature indicator in the stem and consequently might not be at the same temperature as the mercury in the bulb. While this effect is small for mercury, where the bulb volume is 6250 times the volume of the mercury in a 1°C length of the capillary stem, thermometers used in partial immersion often need correcting.

The bore in the stem needs to be smooth and uniform. An allowed departure from uniformity is a contraction chamber that, by taking up a volume of the expanding mercury, allows the overall length of the thermometer to be kept a reasonable size. The chamber shape must be very smooth to prevent bubbles of gas being trapped. An auxiliary scale is usually added for the ice point if a contraction chamber is used.

The marked scale allows the user to read the column length as a temperature. For a well-made thermometer, the change in length is proportional to the change in volume and hence to the temperature, as per Equation 32.131. In order to make the scale, the manufacturer first places “calibration” marks on the thermometer stem, as shown in Figure 32.71. Depending on the range and accuracy, more than two calibration marks can be used and, thus, the thermometer stem is divided into segments. A ruling engine is then used to rule a scale between each pair of marks, with careful alignments between the adjacent segments if they occur. The scale rulings will be spaced to approximate Equation 32.131 to the accuracy expected for the thermometer type. A good indicator of the quality of a thermometer is how close these calibration scratches are to the scale markings.

Because of the segmented ruling, it pays to check that the scale markings are uniform in appearance with no obvious glitches. Quite marked discontinuities in the scale are sometimes found. The markings are individual to each thermometer and the total scale length can vary from thermometer to thermometer. This can be an inconvenience if a thermometer has to be replaced; but fortunately, most quality thermometer specifications restrict the amount of variation permissible.

FIGURE 32.71  Calibration marks are usually scratched on at both ends of a thermometer’s scale to locate the ruling of the scale. Left: A good quality thermometer. The calibration mark is immediately alongside the 0°C mark. Right: A general-purpose thermometer. Here, the calibration mark is about ¼ scale division above the 50°C mark. Since it is a cheaper thermometer, the manufacturer is content to locate the scale within the ¼ scale division, and this would vary from thermometer to thermometer in the same batch. Readings could be expected to be accurate to about one scale division, 0.5°C in this instance.
Time-Constant Effects

The time constant is determined almost entirely by the diameter of the bulb because heat must be conducted from the outside to the center of the bulb. A typical bulb of diameter 5 mm has a relatively short time constant. The length of the bulb is then determined by the sensitivity required of the thermometer, given that there is a minimum useful diameter for the capillary bore.

The choice of bore diameter is a compromise involving several error effects. A large-diameter bore requires a larger volume bulb to achieve a given resolution, thus increasing the thermal capacity. A small-diameter bore not only becomes difficult to read but also suffers from stiction — the mercury moving in fits and starts due to the surface tension between the mercury and the bore wall. Stiction should be kept less than 1/5 of a scale division.

Table 32.22 gives the 1/e time constants in various media for a 5-mm diameter bulb. Time constants for other diameters can be estimated by scaling the time in proportion to the diameter. The table clearly indicates that the thermometer is best used with flowing (or stirred) fluids.

Thermal Capacity Effects

Glass thermometers are bulky and have considerable mass, especially high-precision thermometers that have a long bulb. The high thermal mass or heat capacity can upset temperature measurements, making high precision difficult. Inappropriate use of liquid-in-glass thermometers occurs when the thermometer is too massive to achieve the precision required. Preheating the thermometer can alleviate the worst of the problem. For higher precision and low mass, choose a platinum resistance thermometer or thermistor instead.

Simple estimates of the heat requirements are made by measuring the volume of thermometer immersed, and assuming that 2 J are required to raise 1 cm³ of the thermometer volume (glass or mercury) by 1°C.

Separated Columns

A common problem is for a part of the thermometric liquid in the stem to become separated from the main volume. While this will show as an ice point shift, it is still important to make a simple visual check when using the thermometer.

With organic liquids, the problem might be more difficult to identify because liquid adheres to the surface of the capillary and may not be visible. Spirit thermometers need to be held vertically to allow the thermometric liquid to drain down. Warm the top of the thermometer to prevent condensation of any vapor. Allow time for drainage of the liquid in the thermometer if the temperature is lowered quickly (approximately 3 min per centimeter). Cool the bulb first in order to keep the viscosity of the liquid in the stem low for better drainage.

For mercury, the separation is usually visible. Two causes can be identified: boil-off and mechanical separation (Figure 32.72).

To help retard the boil-off of mercury vapor at high temperatures (e.g., above 150°C), the capillary tube is filled with an inert gas when manufactured. Usually, dry nitrogen is used under pressure to prevent
oxidation of the mercury. The expansion chamber must be kept cooler than the bulb to prevent a high pressure build-up. The high pressure can permanently distort the bulb even if rupture does not occur.

Mechanical separation of the liquid column is, unfortunately, a common occurrence, particularly after shipment. A gas fill will help prevent this separation but, conversely, the gas makes it more difficult to rejoin. There is also a risk of trapped gas bubbles in the bulb or expansion chambers and careful inspection is needed to locate them. A vacuum in the capillary tube will give rise to more breaks, but they are easily rejoined.

With care, it is often possible to rejoin the column and still have a viable thermometer. However, it must be realized that attempts to join a broken column could also result in the thermometer being discarded if the procedure is not successful. Column breaks that occur only when the thermometer is heated often require that the thermometer be discarded.

Various procedures for joining a broken mercury column can be tried. The procedures below are given in order of preference.

- Lightly tap the thermometer while holding it vertically. This may work for a vacuous thermometer.
- Apply centrifugal force, but avoid a flicking action, and be careful to avoid striking anything. This can be best done by holding the bulb alongside the thumb, protecting it with the fingers, and with the stem along the arm. Raise the arm above the head and bring it down quickly to alongside the leg.
- If both the above are unsuccessful, a cooling method can be attempted. This method relies on sufficient cooling of the bulb for all the mercury to contract into the bulb, leaving none in the

FIGURE 32.72  A typical break in the mercury column of a thermometer.
stem. The column should be rejoined when it has warmed to room temperature. Carry out the warming slowly so that all the mercury is at the same temperature. More than one attempt might be needed. The first two methods might also need to be applied to assist movement of the mercury.

Three cooling mediums readily available are:

1. Salt, ice, and water (to –18°C)
2. Dry ice, i.e., solid CO2 (–78°C)
3. Liquid nitrogen (–196°C)

The last two refrigerants require more care as they could freeze the mercury. An excessive cooling rate could stress the glass. Cold burns to the user could also occur.

If the broken column has been successfully rejoined, then an ice point (or other reference point) check should be made. If the reading is the same as obtained previously, then the join can be considered completely successful and the thermometer ready for use. (It is essential to keep written records here.) However, a significant ice-point shift indicates that the join was not successful and that the thermometer should be discarded. If the ice-point shift is within that specified for the thermometer type, then treat the thermometer with suspicion until there is evidence of long-term stability, i.e., no significant ice-point changes after use.

Immersion Errors

It was previously mentioned that problems are expected if not all the liquid in a liquid-in-glass thermometer is at the same temperature as the bulb. Because the scale must be read visually, liquid-in-glass thermometers are used at various immersion depths, which results in different parts of the thermometric liquid being at different temperatures. In addition, the clutter around an apparatus often necessitates the thermometer being placed in a nonideal position.

Three distinct immersion conditions are recognized for a liquid-in-glass thermometer, and each requires a different error treatment. Figure 32.73 illustrates the three conditions.

• Complete immersion: By definition, if the complete bulb and stem are immersed at the same temperature, the thermometer is completely immersed. This condition is not common, except at room temperature, and should be avoided at higher temperatures. High pressure build-up in the thermometer can cause it to rupture, spreading deadly mercury vapor throughout the laboratory. Laboratories where there is a danger of mercury exposure to high temperatures should be kept well ventilated. In other words, DO NOT put a mercury thermometer completely inside an oven to measure the temperature. Specialized applications that use complete immersion, take into account pressure effects on the thermometers.

• Total immersion: Total immersion applies to the situation where all the thermometric liquid, i.e., all the mercury in the bulb, the contraction chamber, and the stem, is at the temperature of interest. The remaining portion of the stem will have a temperature gradient to room temperature (approximately). Especially at high temperatures, the expansion chamber should be maintained close to room temperature to avoid pressure build-up. A very small part of the mercury column can be outside the region of interest, to allow visual readings to be made. The error introduced by this can be estimated by the procedures given below for partial-immersion thermometers. Obviously, the thermometer will have to be moved to allow a range of temperatures to be measured. Total-immersion thermometers are generally calibrated at total immersion and therefore do not need additional corrections.

• Partial immersion: One way around the problem of scale visibility and the need to move the thermometer is to immerse the thermometer to some fixed depth so that most, but not all, of the mercury is at the temperature of interest. The part of the mercury column not immersed is referred to as the emergent column. Corrections will be needed to compensate for the error arising from the emergent column not being at the same temperature as the bulb. Many thermometers are
designed and calibrated for partial immersion and are marked accordingly on the stem with an immersion depth or an immersion line (see Figure 32.70).

A partial-immersion thermometer is properly defined when the temperature profile of the emergent column is also specified. Usually, an average stem temperature is quoted to represent the temperature profile of the emergent column. Thermometer specifications can define the expected stem temperature for a set of test temperatures, but they do not usually define stem temperatures for all possible readings.

A measure of the stem temperature is required if the accuracy of the thermometer reading is to be assessed. The traditional way to measure the stem temperature is with a Faden thermometer. These are mercury-in-glass thermometers with a very long bulb, and various bulb lengths available. The bulb is mounted alongside the part of the stem containing the emergent column with the bottom of the bulb in the fluid. An average stem temperature is obtained as indicated by the Faden thermometer. Other ways of measuring the temperature profile are to use thermocouples along the length of the thermometer, or

FIGURE 32.73 Three types of immersion conditions used for liquid-in-glass thermometers. The preferred immersion condition is usually marked as a line or distance on the stem for partial-immersion thermometers or is given by the thermometer specification.
even several small mercury-in-glass thermometers. The stem temperature can be calculated as a simple average; but strictly speaking, it should be a length-weighted average.

Because the measured stem temperature might not be the same as that given on the calibration certificate, it is necessary to make corrections for the difference. For partial immersion thermometers, the true temperature reading \( t \) is given by:

\[
t = t_i + N \times \left( t_2 - t_1 \right) \times k
\]

(32.132)

where

- \( t_i \) = Indicated temperature
- \( N \) = Length of emergent column expressed in degrees, as determined by the thermometer scale
- \( t_2 \) = Mean temperature of the emergent column when calibrated (i.e., the stem temperature on a certificate for partial immersion or the thermometer reading for a total-immersion certificate)
- \( t_1 \) = Mean temperature of the emergent column in use
- \( k \) = Coefficient of apparent expansion of the thermometric liquid used in the glass of which the thermometer stem is made

See Table 32.21 for suitable values to use for normal temperature ranges.

The use of Equation 32.132 with typical \( k \) values from Table 32.21 is estimated to give a 10% accuracy for the correction. Consequently, the correction is a major source of uncertainty for large temperature differences.

Figure 32.74 gives a chart derived from Equation 32.132 for mercury thermometers that enables the stem correction to be determined graphically. One should become familiar enough with it to make quick estimates in order to determine whether the immersion condition error is significant and therefore needs correction.

Thermometers are usually calibrated at their stated immersion conditions and the actual stem temperatures during calibration are measured and quoted on the certificate. In many applications, a thermometer is used for a standard test method (such as specified by the ASTM or IP). For these instances, the expected stem temperature is specified and there is no requirement for the stem temperature to be measured. The user will, however, need to adjust the certificate correction terms to the immersion conditions of the specification in order to see that the thermometer corrections meet the appropriate quality criteria.

The chart of Figure 32.74 is useful, either to find corrections or to show faults with a particular measurement method. For example, consider the case of measuring boiling water in a beaker with a total-immersion thermometer. The thermometer is too long to immerse and the water level is around the 20°C mark. The emergent column is therefore 80°C long and one assumes that the stem is close to room temperature of 20°C, resulting in an 80°C temperature difference from calibration conditions. On the chart, one finds that the intersection of the 80°C emergent line and the 80°C difference line gives a correction value of just over 1°C. If this value is unacceptable, then clearly a redesign of the measurement method is warranted. More detailed examples can be found in the text of Nicholas and White [5].

**Organic Liquids**

Thermometers with organic liquids have three possible uses:

- To measure temperatures below –38°C
- In situations where mercury is to be avoided
- For inexpensive thermometers

The utility of spirit thermometers is limited because of the lower achievable accuracy, the high nonlinearities, and the volatile nature of the liquids. Organic-liquid thermometers are also difficult to read because of the very clear liquid and concave meniscus. However, the use of a suitable dye and wide bore
can give them as good a readability as mercury. Follow the recommendations of the section on Separated Columns and the section on Storage to get the best result from organic-liquid thermometers.

Storage

Most mercury-in-glass thermometers can be stored horizontally on trays in cabinets, care being taken to avoid any weight or pressure on the bulbs (one reason for the horizontal position). Avoid vibration. Corrugated cardboard, or similar material, can be used as a liner for a tray to prevent the thermometers from rolling.

Thermometers whose main range is below 0°C are better stored vertically, bulb down, in a cool place, but do not rest the thermometer on its bulb. This particularly applies to organic-liquid thermometers, which also should be shielded from light sources, as ultraviolet radiation can often degrade the liquid. If the top of the bore of a spirit thermometer is kept at a slightly higher temperature than the rest of the thermometer, then the volatile liquid will not condense in the expansion chamber.
High Accuracy

If a higher accuracy than 0.1°C is sought, the user will need to not only consult the references [4, 5], but also consult their calibration laboratory. Not all authorities give the same advice on how to achieve higher accuracy. It is important to apply very consistent procedures in line with the calibration. Below are the more important factors that will need further consideration.

Control of the hysteresis effect is important. The thermometers should not be used for 3 days after being exposed to elevated temperatures. Residual effects may be detectable for many weeks. That is, temperature measurements must always be made under rising temperature conditions. Three days is needed for the glass to relax, and in some cases, prolonged conditioning at a fixed temperature is required.

Avoidance of parallax reading errors is important because interpolation of the finer scale is essential. Optical aids are used, but they increase the parallax error. Good mechanical alignment is therefore required to keep parallax to a minimum.

The pressure on the bulb due to the length of mercury in the stem becomes important. Thermometers will give different readings in the horizontal and vertical positions. External pressure variations should also be considered.

In general, total immersion use of the thermometer is required to achieve the higher accuracy.

Defining Terms

See Figure 32.70 for an illustration of the terms used to describe the parts of a liquid-in-glass thermometer.

Emergent column:  The length of thermometric fluid in the capillary that is not at the temperature of interest.

Ice point:  The equilibrium between melting ice and air-saturated water.

Thermometric liquid:  The liquid used to fill the thermometer.

32.9 Manometric Thermometers

Franco Pavese

Manometric thermometers are defined in this Handbook as those thermometers that make use of the pressure of a gaseous medium as the physical quantity to obtain temperature. Very seldom are they available from commercial sources; for example, the temperature control of a home freezer is often of this kind. Consequently, instead of simply buying one, every user must build his own if this kind of thermometer is needed. They can be a quite useful choice since, in the era of electronic devices and sensors, it is still possible to make a totally nonelectronic thermometer, which in addition keeps its calibration indefinitely, as long as the quantity of substance sealed in it remains unchanged. The range of temperatures that can be covered by this kind of thermometer depends on the principle and on the substance used. When the thermodynamic equilibrium between the condensed phase of a substance (either liquid or solid) and its vapor is used, one has a "vapor-pressure thermometer" and the temperature range spanned by each substance is generally narrow. In addition, only substances that are gaseous at room temperature (i.e., condensed at temperatures lower than 0°C) are normally used, confining the working range to below room temperature; however, some substances that are liquid at room temperature and have a high vapor pressure (i.e., which easily evaporate) have bee used, but do not result in a sizable extension of the working range much above room temperature. A special case of vapor pressure being used at high temperature is the device called a "heat pipe," which is not used as a thermometer, but instead as an accurate thermostat [1]; using sodium, the working range is pushed up to ~1100°C. When a pure substance is used only in its gaseous state, one has a "gas thermometer," whose temperature range can be very wide, especially for moderate accuracy, depending mainly on the manometer; on the other hand, its fabrication is somewhat more complex and its use less straightforward.

Both thermometers can be built to satisfy the state-of-the-art accuracy of national standards (uncertainty better than ±0.001 K) or for lower accuracies, down to an uncertainty of ±1% or higher. Both thermometers require the measurement of pressure, in the range from less than 1 Pa up to 100 bar. Directions about the choice of the manometer can be found in Chapter 5.1 of this Handbook. A complete and specialized treatment on both vapor-pressure and gas thermometers up to room temperature and on pressure measurement instruments and techniques for gaseous media can be found in [2]. Gas thermometry above room temperature is treated in [3, 4].

In consideration of the fact that these kinds of thermometers typically must be built by the users, the following will concentrate on the basic guidelines for their design and fabrication.

Vapor Pressure

Figures 32.75 and 32.76 show the pressure values and the sensitivities in the temperature range allowed for each of the most common gaseous substances, considering also, in addition to the liquid phase, the use of the solid phase (where vapor pressure is lower) below the triple point. The lower end of the range is determined by the manometer uncertainty (for a given accuracy), the upper end by the full-scale pressure of the manometer (or by the full evaporation of the condensed phase).

Table 32.23 reports "certified" vapor pressure equations, linking the measured pressure p to the unknown temperature T. The reader might prefer them to the plethora of equations found in the literature, since they have been checked by official bodies and T is expressed in the ITS-90, the International Temperature Scale [5, text in 2]. More checked equations can be found in [6].

Figure 32.77 shows the general layout of a vapor-pressure thermometer. The fabrication of a vapor-pressure thermometer is not exceedingly difficult if a few guidelines are followed. Table 32.24 summarizes the most critical ones — design criteria and filling information — in a compact form [2]. Much more constructional details can be found in [1, 3]. In most cases, the manometer is located at room temperature, and the bulb is connected to it via a small-bore tube (the "capillary tube") without critical drawbacks. The accuracy of these thermometers ranges from ± 0.0001 K using very pure substances in calorimeters and precision mercury manometers, to ≈±1% using dial manometers.
Gas Thermometry

The layout of Figure 32.77 also applies to the design of a constant-volume gas thermometer (more common than the constant-pressure type), with the differences indicated in the relevant caption. The lower temperature end of the working range of a gas thermometer is stated, well before condensation of the substance takes place, by the increase of the uncertainty due to the increase in the nonideality of the gas — i.e., deviation from linearity of the relationship $p(T)$ — which takes place when approaching the condensed state or for increasing gas densities, or due to excessive absorption of gas on the bulb surface, thereby changing the quantity of the thermometric substance. All these conditions act at the lower end of the range. The upper end is stated by technological reasons or by the manometer full-scale capability. The best substances are, as listed, helium (either isotopes), hydrogen, and nitrogen.

From a design point of view, Table 32.25 summarizes the most critical issues. The major problem, apart from gas purity and ideality, is meeting the constant-volume requirement. Being that the manometer is generally at room temperature, the fraction of gas filling the connecting “capillary” tube is subtracted from the total amount of thermometric substance amount filling the system, and since this fraction is not constant, but depends on temperature and on technical conditions, it tends to increase the measurement uncertainty, which is contrary to the case of the vapor-pressure thermometer; this error is called the dead-volume error. Also, the bulb volume itself changes with temperature, due to thermal expansion and, to a much smaller extent, to the change in internal pressure. Design and fabrication criteria and measuring procedures are given in great detail in [2]. The case where the gas thermometer is calibrated at a number of fixed points is also described, with a discussion of the simplification in the use of the gas thermometer introduced with this instrument (called the interpolating gas thermometer, defined in the ITS-90 for use between 3 K and 26 K).

\(^3\) These values are for neon with an isotopic composition close to that specified in the ITS-90 definition.

\(^4\) Above 100 K. It increases to 15 mK at 91 K, and to 10 mK near the critical point.
FIGURE 32.77  The general layout of a manometric thermometer. It is shown with a cryogenic diaphragm pressure transducer; when the transducer is placed instead at room temperature, the bypass valve is also placed at room temperature. Vapor-pressure thermometer: the diameter of the pressure tube increases in steps when pressures lower than \( \approx 10 \) Pa must be measured, in order to decrease the thermomolecular pressure drop. Gas thermometer (constant-volume): the diameter of the pipes connecting the bulb to the cryogenic pressure transducer must be small in order to reduce the so-called “dead-volume.” This requirement is much more stringent when the pressure transducer is moved up to room temperature. In this case, in order to reduce the error due to the “dead-volume,” the bulb volume must be increased significantly.

1. Choice of working substance:
   - Temperature range: Each substance spans only a narrow temperature interval. $T_{\text{max}}/T_{\text{min}} < 2–3$ (including solid-vapor range), except helium. The limit:
     - $T_{\text{max}}$ set by maximum manometer pressure.
     - $T_{\text{min}}$ set by manometer sensitivity.
   - Accuracy:
     - Manometer: No single manometer spans whole range from \( \approx 1 \) Pa (\( dp/dT = 100 \text{ Pa K}^{-1} \)) and critical point (\( p_{c} > 10^{6} \) Pa, except helium) with high or constant accuracy, or with sufficient sensitivity.
     - Substance: Not all substances allow for maximum accuracy, due to purity or to thermal problems related to a low thermal diffusivity value.

2. Choice of pressure measuring system:
   - Sensitivity and accuracy must be matched to the range of \( dp/dT \) and of \( p_{c} \), i.e., \( T \), to be measured.
     - Without separating diaphragm: Can be used only for low to medium accuracy, as thermometric gas also fills the entire manometric apparatus, with problems of contamination and increases in vapor volume.
     - Dial manometers: Used only for accuracy > $\pm 1\%$.
     - Metal diaphragm or bellows (electronic) manometers: Can achieve a $\pm 0.1–0.03\%$ accuracy.
– Quartz bourdon gages: can approach a ±0.01% accuracy, but helium leaks through quartz.
– Cryogenic pressure transducers: None commercially available with accuracy better than ±0.1% (after cryogenic calibration). Eliminate need of the connecting tube in sealed thermometers, but transducer must withstand high room-temperature pressure.

• With separation diaphragm: Mandatory for high or top accuracy. Only zero reproducibility and a moderate linearity near zero are important.
– Capacitive diaphragms: Several commercial models, when properly used, allow zero sensitivity and reproducibility better than ±0.1 Pa.
– Cryogenic diaphragms: Only laboratory-made diaphragms available, some with high zero reproducibility. Allow to confine thermometric gas at low temperatures, but the tube connecting the diaphragm to room-temperature manometer is still necessary.

Room-temperature manometers: When a cryogenic diaphragm is used, only manometers allowing helium as manometric gas can be used.

3. Choice of sealed vs. “open” thermometer:
• Sealed: Low-accuracy only (e.g., dial) thermometers.
– Medium-accuracy sealed thermometers still very simple when using cryogenic manometer and reducing vapor volume, but room-temperature pressure can be higher than 10 MPa. Therefore, only low-sensitivity manometers can be used and thermometer measures only upper part of vapor-pressure scale.
– High-accuracy sealed thermometers can be made, using ballast room-temperature volume and precision room-temperature diaphragm.
• “Open”: Vapor-pressure thermometers using gases are open only since working substance does not stay permanently in working bulb, but (new) samples are condensed in it only during measurements. Requires permanent use of a gas-handling system.

4. Gas purity, isotopic composition and spin equilibrium:
• Purity: Must be known, and possibly checked, e.g., by performing a triple-point temperature measurement. Dew-boiling point difference measurement must also routinely be performed, before sealing in the case of sealed devices.
• Isotopic composition: Some gases show irreproducibility in results due to sample-to-sample changes in isotopic composition. It is impossible to obtain top accuracy with these substances, unless pure isotopes are used.
• Spin equilibrium: With some gases, showing different spin species, equilibrium must be ensured with use of a suitable catalyst.

Problems only for high accuracy Kr, Xe H2, D2

5. Thermometer filling:
• Amount of substance \( n_{\text{max}} \) at \( T_{\text{min}} \):

\[
\frac{\rho_{\text{max}}}{M \ T_{\text{min}}} \left[ \frac{2V \ T_{\text{min}}}{T_{\text{min}} + T_{\text{max}}} + V \right] + \frac{V}{M} \rho_{\text{min}}
\]

• Amount of substance \( n_{\text{min}} \) at \( T_{\text{max}} \):

\[
\frac{V}{M} \left[ \frac{2V \ T_{\text{min}}}{T_{\text{min}} + T_{\text{max}}} + V \right] + \frac{T}{T_{\text{max}} - V_{i}} + \frac{V}{T - V_{i}}
\]

• Bulb volume \( V_{b} \):

\[
V_{b} \left[ \frac{\rho_{\text{min}}}{M \ T_{\text{min}}} - \frac{\rho_{\text{max}}}{M \ T_{\text{max}}} \right] \leq \frac{V}{T_{\text{min}}} \left[ \frac{\rho_{\text{min}}}{M} - \frac{\rho_{\text{max}}}{M} \right] + \frac{V}{M} \left[ \frac{\rho_{\text{min}}}{M} - \frac{\rho_{\text{max}}}{M} \right]
\]

\[
+ \frac{2V}{R} \left[ \frac{\rho_{\text{min}}}{T_{\text{min}} + T_{\text{max}}} - \frac{\rho_{\text{max}}}{T_{\text{min}} + T_{\text{max}}} \right] + \frac{V_{i}}{T_{\text{min}} + V_{i}}
\]

to a first approximation the terms in bold can be omitted.

It follows:

\[ V_{i} \geq \approx 2 \text{ cm}^3 \]

Taking the minimum volume

\[ 0.074 \geq n \]

\[ n \geq 0.034 \]
Calculation of the amount of substance \( n \) to condense in the thermometer: the gas is stored at \( p_r \) in the room-temperature reservoir of volume \( V_r \). When the substance is condensed in the thermometer bulb at a temperature \( T_f \), a residual \( n_o = \frac{p_r V_r}{R T_f} \) remains in \( V_r \). Therefore, in order to condense a quantity \( N \), one must have in the system:

\[
\nu' = \frac{P V_r}{R T_r} \left( 1 - \frac{P_c}{P_r} \right) + \left( V_r + V + V_b \right)
\]

Symbol caption: \( V^c = \text{volume of the liquid phase}; \ p = \text{density}; \ p = \text{pressure}; \ V = \text{volume}; \text{subscript } r = \text{room temperature, } c = \text{capillary, } b = \text{bulb.}

| TABLE 32.24 (continued) Summary of Design Criteria for Vapor-Pressure Thermometers |
| In order to seal-in 0.05 mol, the filling system must contain 0.069 mol |

1. Choice of temperature range and of span \( T_{min} \leftrightarrow T_{max} \):
   - Below 273.16 K, \(^4\)He gas thermometry is limited down to 2.5 K. With \(^4\)He, accurate virial corrections available down to 1.5 K.
   - Only CVGTs of special design can be used in full span. Being that \( p \mu T \), the 2.5 K to 273.16 K range corresponds to \( p_{max}/p_{min} > 100 \). For top accuracy, \( \frac{dp}{p} < 0.01\% \), corresponding at \( p_{min} \) to \( \frac{dp}{p} < 10^{-6} \). \( p_{max} \), generally not achievable.
   - Being that \( p \mu n/V \), molar density must generally be changed over the range to optimize accuracy, but \( n/V \) must be limited to avoid third virial correction, especially below \( \approx 2 \) K.
   - In general, a CVGT is designed for work only below or only above a temperature between 25 K and 100 K.

2. Choice of reference temperature \( T_0 \):
   - Truly absolute thermometer: only one choice possible — 273.16 K.
     - Two-bulb CVGT: Avoids necessity to bring up to \( T_0 \) the bulb measuring \( T_{min} > T < T_{max} \). Useful with thermometers designed for use at \( T \approx T_0 \).
     - Single-bulb CVGT: Same bulb spans the entire range up to \( T_0 \).
   - Low-temperature reference temperature \( T_0' \) (from 25 K to 90 K):
     - Single-bulb CVGT commonly used. \( T_0' \) value assigned by an independent experiment, and, therefore, not exact by definition. However, the additional uncertainty is a minor inconvenience with respect to the advantage of limiting bulb temperature within the span \( T_{min} \leftrightarrow T_{max} \).

3. Choice of thermometric gas and filling density:
   - Thermometric gas:
     - Nitrogen: Low-medium accuracy.
     - \( e \)-Hydrogen: Not used for over 50 years, but still suitable for low-medium accuracy and temperature range above \( \approx 20 \) K.
     - Helium-4: Commonly employed in recent gas thermometers. Use limited to above 2.5 K.
     - Helium-3: Considered more in modern gas thermometry. Use presently limited to above 1.5 K; potential for use down to \( < 1 \) K.
   - Filling density: \( p \approx n/V \) and \( dp/dT \approx n'/V' \) (1 kPa K\(^{-1} \) \( \approx 121 \) mol m\(^{-3} \)). Always advantageous increasing \( n/V \) up to an upper boundary set by need of third virial correction. As a rule, \( n/V < 250 \) mol m\(^{-3} \) above \( \approx 2.5 \) K, \( n/V < 160 \) mol m\(^{-3} \), down to 1.2 K and \( n/V < 30 \) mol m\(^{-3} \) at 0.8 K.

4. Choice of the pressure measuring system:
   - See Table 32.24.

5. CVGT parameter design:
   - A. Room-temperature pressure transducer
     - Bulb: Top accuracy, 1 L volume typical; low accuracy, as low as 50 cm\(^3\).
     - Dead-volume: Top accuracy, <10 cm\(^3\); low accuracy: up to 10% of bulb volume.
   - B. Cryogenic pressure transducer
     - No difference with respect to a vapor-pressure thermometer.

6. Bulb design:
   - Volume may not be constant, because of:
     - Compression modulus: Walls must be thick to limit deflection due to pressure, or bulb must be enclosed in a guard chamber kept at bulb pressure. Stress in bulb material must be relieved by annealing after machining.
Temperature Indicators

Jan Stasiek, Tolestyn Madaj, and Jaroslaw Mikielewicz

Temperature indicators serve for approximate determination of bodies’ temperatures and are used to control a variety of temperature treatment processes. The temperatures are determined based on knowledge of characteristic rated temperatures, which are mean critical temperatures of the indicator. However, it should be stressed that the accuracy of these measurements is satisfactory only if the measurement conditions are similar to the standard conditions for which the temperature indicators were calibrated. Otherwise, the critical temperatures of the indicators can be different from their rated temperatures listed in the standards and the measurements can have considerable errors.

The temperature indicators can be classified into two groups, each group using different physical properties for the determination of the temperature. The indicators belonging to the first group melt at certain temperatures. For some of these indicators, such as pyrometric cones, thermoscope bars and rings, the process of melting manifests itself as a shape/size deformation for which the temperature is

determined by measuring the degree/rate of deformation of the indicator. For others, such as melting pellets, liquids, crayons, and monitors, the melting means turning entirely into a liquid smear. This can also be accompanied by color changing. The second group consists of color-change indicators containing pigments that at different temperatures, show different colors by selectively reflecting incident white light. Among this group are reversible and irreversible paints, color-change crayons, and liquid-crystal indicators.

Melting and Shape/Size Changing Temperature Indicators

The latest British Standard BS 1041, Part 7, 1988 [1] lists the following temperature indicators: Seger cones, thermoscope bars, and Bullers rings. Some temperature indicators used in the past — such as Watkin cylinders and Holcroft bars — are no longer used and are of historical value only. In the U.S., melting pellets, crayons, liquids and monitors are available on the market and widely used.

The rated temperature for Seger cones (pyrometric cones) and thermoscope bars is defined by appropriate shape deformation resulting from the transformation of a certain amount of the indicator substance from the solid to liquid state. For chemically pure elements and compounds at a constant pressure, the temperature during the entire process of phase change remains constant. If the pressure changes within the range of changes for atmospheric pressure, then the temperature changes are insignificant and can be neglected even during precise measurements. The pyrometric cones and thermoscope bars are prepared from complex mixes of frits, fluxes, clays, calcium and magnesium compounds, silica, etc. The melting temperatures of the indicators, also referred to as the critical or rated temperatures, vary with the proportions of the above compounds. Therefore, a set of indicators differing in the proportions of the compounds is capable of covering a required range of rated temperatures. The melting temperatures can also change, to a degree, with the proportion of phases. For mixes that constitute pyrometric cones and thermoscope bars, the temperature difference between the beginning and the end of the melting process can be as large as 25 to 40°C. At the rated temperature, one can assume that the temperature is either at the beginning or at the end of the melting process. In practice, an intermediate value is assumed, referring to an expected shape deformation of the temperature indicator.

For Bullers rings, the rated temperature is determined by a shape deformation that can be described as a temperature shrinkage. An indication of the required temperature is a proper contraction of the outer diameter of the ring made of special clay (a mix of appropriate materials) that contracts uniformly with the increase in temperature throughout the operating range.

For melting pellets, crayons, liquids, and monitors, the rated temperature is that of the beginning of the melting process when the indicator turns entirely into a liquid smear. Usually, on cooling, the liquid mark solidifies and becomes glossy-transparent or translucent in appearance. The entire process can be accompanied by a change in color — mostly because the color of the workpiece surface or the back of an adhesive label, which enables the contact of the indicator with the surface, will show up from under the transparent mark. However, the moment of melting — not a color change — is the temperature signal.

Seger Cones

The pyrometric cones are typically slender, truncated, trihedral pyramids, about 25 mm to 60 mm in height. The base of the pyramid is a regular triangle of side 7 mm to 16 mm. One edge of the pyramid is vertical or slightly leaned outward (see Figure 32.77a). The recommended height of the standard cones is 60 mm; the laboratory cones are 30 mm high.

The pyramids are manufactured by pressing a powder mixture of a number of minerals mixed in different proportions throughout the required range of rated temperatures. The main components are silicon oxide (SiO₂), aluminium oxide (Al₂O₃) with additives in the form of oxides (MgO, K₂O, Na₂O, CaO, B₂O₃, PbO), and an organic binder. The following equation is an example of chemical constitution of the pyrometric cone for the temperature range of 600°C to 900°C:

\[ X(2\text{SiO}_2 + \text{Al}_2\text{O}_3) + (1 - X)(0.5\text{Na}_2\text{O} + 0.5\text{PbO} + \text{B}_2\text{O}_3 + 2\text{SiO}_2) \]
where $X$ is a mass unit. The pyramids designed for higher rated temperatures are prepared based on similar equations.

Touch-down Temperatures for Seger Cones.
As the heating progresses, the cone used for the measurement begins to soften and bends until its tip touches down on the surface on which it was placed. The rated temperature referring to this deformation is called the touch-down temperature. The touch-down temperatures for the Seger cones are determined in an electric kiln with clean atmospheric air at a heating rate of 60°C h$^{-1}$.

According to the earlier German standard DIN 51063 [2], the range of touch-down temperatures from 600°C to 2000°C at 10 to 50°C steps is covered by a series of Seger cones denoted traditionally by numbers from 022 to 42 (see Table 32.26a).

According to the latest British Standard BS 1041, Part 7, 1988, the touch-down temperatures within the range of 600°C to 1535°C at temperature intervals of 15 to 35°C are realized by a series of Seger cones numbered from 022 to 20 (see Table 32.26b).

The precision of determination of the touch-down temperatures for the industrial cones should be better than ±15°C; for the laboratory cones, better than ±10°C. If the heating rate undergoes change
within the range of 20 to 150°C h⁻¹, then the rated temperatures can change by –40°C for the above lower limiting value of the heating rate up to 60°C for the upper value. A 0.35% content of SO₂ in the atmosphere increases the rated temperatures by about 35°C. Also, the presence of soot in the atmosphere slightly raises the rated temperatures.

How to Use the Materials.
While single cones are sometimes used, usually three or four consecutively numbered cones, including a cone whose rated temperature is equal to the required temperature of the heat treatment and two cones of neighboring numbers (one less and one more) are employed for the temperature determination (see Figure 32.77b). They are installed into specially unfired plaques with tapered holes and protrusions that hold the cones firmly. The plaques are mounted to a workpiece surface to allow observations. A cone can be set up in other ways, such as inserting its base into refractory clay. However, it is necessary to assure a correct angle and firm hold of the cones during the firing cycle. Failure in these respects will

</table>

*Note: 1. Each temperature given in the table is that at which the tip of a cone will bend sufficiently to touch the base in an electric kiln with a heating rate of 60°C h⁻¹. 2. The touch-down temperature depends on the rate of heating: reports on firing behavior should quote the cone number, not the temperature taken from the above table. 3. Intermediate degrees of bending can be referred to the hands of a clock, e.g., 3 o’clock would represent a cone bent halfway to the stand.*
cause the cone to bend unpredictably and give incorrect assessment of the heat treatment. If the process of heating takes place with a standard heating rate, then the rated temperature is reached when the tip of the central cone touches the base of the plaque. With further prolongation of the firing cycle, the cone will melt completely to form a blob on the plaque. The process of reaching the rated temperature is signaled in advance by the cone of one-less number. The cone of one-more number is there to prove that the required temperature value is not exceeded. Placing a series of cones with lower numbers (lower rated temperatures) provides the opportunity to carry out the process of heating at a required rate.

Typical Application.
Seger cones are used for the control of firing processes in the ceramics industry and artistry.

**Thermoscope Bars**
These indicators have the shape of bars of rectangular cross-sections. The typical dimensions of the bars are: length, 57 mm; width, 8 mm; and height, 6 mm. Bars of consecutive numbers (rated temperatures) are placed horizontally on a refractory stand as in Figure 32.78. The set of thermoscope bars is a more convenient and slightly modified form of Holcdorft bars. The bars are made of the same composites (mineral mixes and organic binder) as the pyrometric cones. The mixed powders are pressed and can be hardened by pre-firing at relatively low temperatures, below those at which bending should occur.

Bending Temperatures of Thermoscope Bars.
The rated temperatures of thermoscope bars, referred to as the bending temperatures, are found during the calibration in an electric kiln with a heating rate of 60°C h⁻¹ when the bars start to exhibit deformation (i.e., begin to bend).

According to the British Standard BS 1041, the range of rated temperatures from 590°C to 1525°C at temperature intervals of 15 to 35°C is covered by 42 thermoscope bars (see Table 32.27).

The precision of determination of the bending is about ±15°C; the other properties of the thermoscope bars referring to changes of the standard conditions are the same as for the pyrometric cones.

How to Use the Materials.
Four thermoscope bars of consecutive numbers — the first two having lower bending temperatures, the third one having the bending temperature equal or close to the required temperature, the fourth one having a higher bending temperature — are placed in sequence on a special refractory stand as in Figure 32.78a. The set is mounted to the workpiece surface where observations take place. If the process of heating takes place with a standard heating rate, then the beginning of deformation (bending) of the
third bar indicates that the required temperature is reached. The process of reaching the rated temperature for the third bar is signaled in advance by the deformation of the preceding bars whose behavior allows the evaluation of the heating rate. The unbent fourth bar testifies that the required temperature is not exceeded (see Figure 32.78b).

Typical Application.
The application of the thermoscope bars is identical to that of the Seger cones.

**Bullers Rings**

These temperature indicators in the form of rings have the following dimensions: outer diameter, 63 mm; inner diameter, 22 mm; and width, 8 mm. The appropriate measuring unit consists of a Bullers ring and a specially prescaled device for measurement of the temperature shrinkage of the ring. This contraction gage measures the outer diameter of the heated ring, based on which the heating work is assessed. The full measuring range of rated temperatures from 960°C to 1440°C is covered by four types of rings manufactured by pressing powders of ceramics mixes, with a binder, and without prefiring.

1. Rings denoted as 55 of brown color, suitable for temperatures from 960°C to 1100°C are used in the firing of glost ware and common building bricks where the finishing temperatures are relatively low.
2. Rings numbered 27/84, colored green, suitable for temperatures from 960°C to 1250°C are used for firing earthenware at the medium finishing temperatures, as well as tiles and bricks refractory with respect to low temperatures.
3. Rings numbered 75/84, colored natural, recommended for firing temperatures from 960°C to 1320°C, allow for higher finishing temperatures and are used for firing electrical porcelain, china, grinding wheels, and bricks refractory with respect to higher temperatures.
4. Rings numbered 73, colored yellow, recommended for temperatures from 1280°C to 1440°C for slow firing conditions as used in the manufacture of high-temperature ceramics and heavy refractories.

Approximate rated temperatures for the Bullers rings and corresponding readings of the contraction gage according to the British Standard BS 1041 are presented in Table 32.28.

**How to Use the Materials.**

One or more rings of the same type are placed vertically in a prefired stand and mounted to a workpiece surface. To determine the temperature as the firing progresses, the heated rings are withdrawn from their...
stands, cooled to the ambient temperature, and then measured for contraction. This measurement is carried out on a gage consisting of a brass base plate on which a radial arm with a pointer moving over a scale and two steel dowel pins, against which the ring is pressed by the movable arm, are mounted (see Figure 32.79). A contraction of the ring gives rise to an amplified movement of the pointer over the scale. The divisions on the scale are numbered from –5 to 60. More heavily fired rings contract more and give higher readings on the gage. The divisions below 0 indicate expansion of the ring; above 0 indicates contraction. Rings should be measured across several diameters by turning them around in the gage so as to find the mean value to which the temperature can be assigned with the help of Table 32.28. Placing several rings in the stand in a manner that allows their easy withdrawal gives the possibility of measuring

</table>

Note: These values should be used with caution because they are dependent on the firing cycle to which the rings are subjected.
the heating rate. In a similar way, distribution of a number of rings throughout the furnace enables the
determination of the temperature field in the furnace.

Usually, one or more test pieces from a series of rings are picked out for the sake of calibration so as
to compare the obtained readings with the standard values enclosed in Table 32.28. Intermediate mea-
surements are also carried out to evaluate the effect of the heating rate on the temperature shrinkage of
the rings. The accuracy of the temperature determination for the standard heating conditions is \( \pm 0.5 \) of
a single division of the scale.

Typical Application.
The application of the Bullers rings is similar to the Seger cones and thermoscope bars. An inconvenience
is the fact that the Bullers rings require gage measurements and the temperature cannot be solely
determined based on naked-eye observations.

**Temperature-Indicating Pellets, Liquids, Crayons, and Monitors**

Temperature-Indicating Pellets.
Temperature-indicating pellets are manufactured by pressing powders of mineral mixes of certain melting
temperatures and an indifferent binder. Melting pellets are recommended as standard tablets \( \phi 7/16 \times 1/8 \)
and miniature tablets \( \phi 1/8 \times 1/8 \) (see Figure 32.80). There are 112 different pellets which cover the
temperature range from 40°C (100°F) to 1650°C (3000°F); see Table 32.29. The accuracy of the temper-
ature determination is \( \pm 1\% \) of the rated temperature. There are also available pellets for temperature
control in strongly reducing atmospheres.

How to Use the Materials.
A pellet of the rated temperature equal to the required temperature of heat treatment is placed on the
investigated surface before the heating starts. When the heating progresses, the beginning of melting

---

*FIGURE 32.79* Contraction gage.
signals that the rated temperature is reached. Placing more pellets with the rated temperatures lower and higher than the required temperature enables more precise control of the heating process.

Typical Application.
Typical applications are checking furnace temperatures, control of heat treating of large units, as well as other applications involving long-duration heating.

Temperature-Indicating Liquids.
Temperature-indicating liquids are solutions of powdered mineral mixes in indifferent highly volatile solvents. They are available for use by brushing or spraying. There are over 100 different liquids with the rated temperatures from 40°C (100°F) to 1371°C (2500°F); see Table 32.29. The accuracy of the temperature determination is ±1% of the rated temperature.

How to Use the Materials.
A thin coating of the liquid is put on the clean and dry surface by brushing or spraying before the heating starts. It dries almost instantly to a dull opaque mark. When the required temperature is reached, this mark liquefies. The melted coating does not revert to its original opaque appearance but remains glossy-transparent on cooling. It should be noted that color changes do not signal the required temperature. The melting, not the color change, is the temperature signal.

Typical Application.
They are recommended for temperature control on fabrics, rubber, plastics, on smooth surfaces such as glass or polished metals, as well as for monitoring critical temperatures in electronic fields.

FIGURE 32.80 Temperature indicating crayon and pellets.
Temperature-Indicating Crayons.

Temperature-indicating crayons are sticks manufactured from powders of mineral mixes of certain melting temperatures and an indifferent binder. The crayons are put in specially adjustable metal holders with labels saying their rated temperatures; see Figure 32.80. Similar to the temperature-indicating liquids, there are over 100 different crayons that cover the temperature range from 40°F (100°C) to 1371°F (2500°C); see Table 32.29. The accuracy of the temperature determination is also ±1% of the rated temperature.

* Series "R" pellets for use in strongly reducing atmospheres.
* Available in pellets only.

Temperature-indicating crayons are sticks manufactured from powders of mineral mixes of certain melting temperatures and an indifferent binder. The crayons are put in specially adjustable metal holders with labels saying their rated temperatures; see Figure 32.80. Similar to the temperature-indicating liquids, there are over 100 different crayons that cover the temperature range from 40°F (100°C) to 1371°F (2500°C); see Table 32.29. The accuracy of the temperature determination is also ±1% of the rated temperature.

**How to Use the Materials.**

During heating, the workpiece should be struck repeatedly by the crayon. Below its rated temperature, the crayon leaves a dry opaque mark. When the rated temperature is reached, the crayon leaves a liquid...
smear. On cooling, the liquid mark will solidify with a transparent or translucent appearance. For temperatures below 700°F, the mark can be put on the workpiece surface before the heating process. The mark will liquefy when the rated temperature is reached. It should be remembered that the moment of melting, not any change in color, is the temperature signal.

**Typical Application.**
The crayons can be applied in welding, forging, heat treating and fabrication of metals, molding of rubber and plastics, wherever the workpiece is accessible during the heating process. Very smooth surfaces are excluded.

**Temperature Monitors (Labels).**
These temperature indicators are adhesive-backed labels with one or more heat-sensitive indicators under transparent circular windows. The indicators turn black (show black paper backing) when the rated temperature is reached. The rated temperatures are from 40°C (100°F) to 320°C (600°F). They are available as single temperature or multi-temperature indicators with 10°, 25°, or 50° steps. The tolerance of the temperature determination is ±1°C (±1.8°F) below 100°C, and ±1% of the rated temperature above 100°C. Exemplary rated temperatures for a series of 4-temperature (4-dot) indicators are presented in Table 32.30. A 4-dot temperature monitor is displayed in Figure 32.81.

![TABLE 32.30 Rated Temperatures for 4-Temperature (4-dot) Labels](image)

**FIGURE 32.81** Four-dot label.
How to Use the Materials.
After removing the backing, the label is pressed firmly to the dry and clean workpiece surface. A change in color to black is the temperature signal. Application of multitemperature-indicating labels allows more precise temperature determination.

Typical Application.
They are especially applied for monitoring the safe operating temperature of equipment and processes, safeguarding temperature-sensitive materials during storage and transport.

The melting temperature indicators are described in the catalogs of their manufacturers [3, 4]. As the melting indicators are widely used in the U.S., temperatures in Fahrenheit are also given.

Color-Change Temperature Indicators
Color-change indicators comprise temperature-indicating paints, crayons, as well as liquid crystal indicators.

Temperature-Indicating Paints and Crayons
Temperature-indicating paints are basically acrylic lacquers containing finely dispersed temperature-sensitive inorganic pigments. The principle of operation of these indicators draws on the change in color of incident light reflected from the surface of the paint due to chemical reactions which the dispersed pigments undergo and creation of new compounds at specific transition temperatures. The color-change temperatures are also determined by the heating time. According to the British Standard, it is assumed that the rated temperatures of the paints correspond to the change in color at a heating interval of 10 min.

To make the characteristics of temperature-indicating paints complete, the manufacturers also provide, together with the paints, graphs of trigger temperature vs. heating time relationships.

Temperature-indicating paints and crayons can be divided into two groups:

• Irreversible indicators: where the change of color becomes permanent
• Reversible indicators: after cooling and some time, they revert to previous colors.

Irreversible color-change indicators are complex compounds containing various metals, including cobalt, chromium, molybdenum, nickel, copper, vanadium, or uranium. However, they are lead- and sulphur-free. They are available on the market in the form of paints and crayons.

Irreversible Color-Change Paints.
The irreversible paints can change color once or several times during the heating process. Thus, another division can be made on single-change and multichange paints. The range of rated temperatures is from 40°C to 1350°C at 10 to 200°C steps. At the standard conditions, the tolerance of measurements is ±5°C for lower temperature values and ±1% for higher temperatures. Exemplary single-change paints with two critical temperatures — the initial trigger temperature for which the paint changes color after 10 min heating, and the cut-off temperature being the lowest temperature for which the color change is achieved for long-duration heating — are collected in Table 32.31. Color changes and critical temperatures for some multichange paints (changing color 2, 3, 3 or 6 times throughout the heating cycle) are presented in Table 32.32.

How to Use the Materials.
A thin layer of the paint is applied to a workpiece surface by brushing or spraying like an ordinary paint and allowed to dry before the heating starts. During the heating, when a point of the surface reaches or exceeds the critical temperature, a color change will take place. To determine the distribution of temperature, a multichange paint can be applied. With a nonuniform temperature rise, a number of colored bands separated by isothermal lines will appear on the workpiece surface, allowing the thermal record to be made of the temperature gradient across the surface.

Typical Application.
The temperature-indicating paints are widely used in industrial applications for observing heat patterns, detecting high and low temperature points on surfaces of heat engines, pipelines, and refrigeration fins.
Color-Change Crayons.
Color-change crayons, available in more than 10 distinct colors, similar in shape to regular crayons for drawing, cover the temperature range from 65°C to 670°C at 10 to 100°C temperature intervals. Exemplary single-change crayons are presented in Table 32.33. The accuracy of the temperature determination is the same as for the temperature-sensitive paints. They can be used for evaluating the temperature on already heated surfaces. They change color 2 min after reaching the rated temperature. Easy to use and inexpensive, they are invaluable for occasional temperature control in auto repairs, soldering, welding, electrical wiring, enameling, and for any operation involving boiling, baking, and other forms of heating.

\(^a\) Color-change temperature for 10-min heating.

They can be also used for controlling temperatures of powered elements and surfaces that are inaccessible or revolve at high speeds.
Reversible Color-Change Indicators.
Reversible color-change indicators are available on the market as paints and in label form. The thermal pigments of these temperature indicators are mercury-based complexes. Therefore, they cannot be applied directly to metal surfaces as this causes decomposition. They also tend to decompose after long exposure to heat, but the decomposition can be retarded by using a clear over-lacquer. The pigments find their most successful application when encapsulated into labels.

The rated temperatures for the reversible color-change paints do not exceed 170°C. For temperatures up to 70°C under standard conditions, the tolerance of measurements is ±1°C; for 70 to 150°C, ±2°C; and for 150 to 170°C, ±3°C.

How to Use the Materials.
A thin layer of a reversible paint is applied to a workpiece surface by brushing or spraying, or a label is pressed to the surface. During the heating, a color change will take place when the temperature of the surface reaches or exceeds the critical temperature.

Typical Application.
The reversible color-change paints are widely used in the electrical industry, especially on busbars, live conductors, and connectors in high-current switches and in electronic fault-finding. They also find application as warning and indicating devices of domestic appliances. They are invaluable for controlling lower temperatures when it is necessary to detect undesirable temperature excursions, correct faults, and revert to normal conditions.

Thermochromic Liquid Crystals
Liquid crystals constitute a class of matter unique in exhibiting mechanical properties of liquids (fluidity and surface tension) and optical properties of solids (anisotropy to light, birefringence). Certain liquid crystals are thermochromic and react to changes in temperature by changing color. They can be painted on a surface or suspended in a fluid and used to make the distribution of temperature visible. Normally clear, or slightly milky in appearance, liquid crystals change in appearance over a narrow range of temperatures called the color-play bandwidth (the temperature interval between first red and last blue), centered around the nominal event temperature (midgreen temperature). The displayed color is red at the low temperature margin of the color-play interval and blue at the high end. Within the color-play interval, the colors range smoothly from red to blue as a function of temperature; see Figure 32.82. Liquid

FIGURE 32.83  Structures of liquid crystals (a) nematic; (b) cholesteric; (c) smectic A; (d) smectic B.
Temperature-Sensitive and Shear-Sensitive Formulations.

Temperature-sensitive liquid crystals show colors by selectively reflecting incident white light. Conventional temperature-sensitive mixtures turn from colorless (or black against a black background) to red at a given temperature and, as the temperature is increased, pass smoothly through the other colors of the visible spectrum in sequence (orange, yellow, green, blue, violet) before turning colorless (or black) again in the ultraviolet at a higher temperature. The color changes are reversible and on cooling the color change sequence is reversed.

Temperature-insensitive (sometimes called shear-sensitive) formulations can also be made. These mixtures show just a single color below a given transition temperature (called the clearing point) and change to colorless (black) above it. The working temperature range is thus below the clearing point. Both reversible and hysteretic (memory) formulations can be made. All liquid crystal mixtures should be viewed against nonreflecting backgrounds (ideally black, totally absorbing) for best visualization of the colors.

Color-Play Properties and Resolution.

Temperature-sensitive thermochromic mixtures have a characteristic red start or midgreen temperature and color-play bandwidth. The bandwidth is defined as the blue start temperature minus the red start temperature. The color play is defined by specifying either the red start or midgreen temperature and the bandwidth. For example, R35C1W describes a liquid crystal with a red start at 35°C and a bandwidth of 1°C, i.e., a blue start 1°C higher, at 36°C; G100F2W describes a liquid crystal with a midgreen temperature at 100°F and a bandwidth of 2°F.

Both the color-play bandwidth and the event temperature of a liquid crystal can be selected by its proper chemical composition. The event temperatures of liquid crystals range from –30°C to 115°C with color-play bands from 0.5°C to 20°C, although not all combinations of event temperature and color-play bandwidth are available. Liquid crystals with color-play bandwidths of 1°C or less are called narrow-band materials, while those whose bandwidth exceeds 5°C are referred to as wide-band. The type of material to be specified for temperature indicating should depend very much on the type of available image interpretation technique — human observers, intensity-based image processing, or true-color image processing systems (see [7]). The uncertainty associated with direct visual inspection is about 1/3 the color-play bandwidth, given an observer with normal color vision — about ±0.2°C to 0.5°C. The uncertainty of true-color image processing interpreters using wide-band liquid crystals is of the same order as the uncertainty assigned to human observers using narrow-band materials, and depends on the pixel-to-pixel uniformity of the applied paint and the size of the area averaged by the interpreter (about ±0.05°C can be achieved). Using a multiply filtered, intensity-based system, the resolution is better than ±0.1°C.

How to Use the Materials.

Liquid-crystal indicators can be used in a number of different forms: as unsealed liquids (also in solutions), in the microencapsulated form (as aqueous slurries or coating formulations), and as coated (printed) sheets. The different forms of the materials have selective advantages and suit different temperatures and flow visualization applications. Individual products are described in more detail in relevant booklets issued by the manufacturers of liquid crystals [5, 6].

Typical Application.

Liquid-crystal indicators are ideal for monitoring temperatures of electronic parts, transformers, relays, and motors. They are invaluable for a fast visual indication of temperatures.

32.11 Fiber-Optic Thermometers

Brian Culshaw

Optical fiber sensing is a remarkably versatile approach to measurement. A fiber sensor guides light to and from a measurement zone where the light is modulated by the measurand of interest and returned along the same or a different optical fiber to a detector at which the optical signal is interpreted. The measurement zone can be intrinsic within the fiber that transports the optical signal, or can be extrinsic to the optical waveguide. The versatility of the fiber sensing medium arises in part because of the range of optical parameters that can be modulated and in part because of the diversity of physical phenomena that involve environmentally sensitive interactions with light.

For example, highly coherent light from a laser source can be introduced into a fiber and its phase modulated by a parameter of interest. The resulting phase changes can then be detected interferometrically. The phase change is simply a modification to the optical path length within the fiber, and can be modulated by shifts in temperature, strain, external pressure field or inertial rotation. A well-designed interferometer can detect $10^{-7}$ radians — equivalent to $10^{-14}$ m!

The laser light could also be Doppler shifted through reflection from a moving object. Its state of polarization can be changed. Its throughput intensity can be modified or the light can be used to stimulate some secondary emissions, which in turn can be monitored to produce the relevant optical signal. If the light is incoherent, then its wavelength distribution (color) can be modified, in addition, of course, to the possibilities for polarization changes and intensity changes.

The physical phenomena capable of imposing this modulation are again many and varied. They include, for example, periodically bending an optical fiber to introduce a localized loss that depends on the sharpness of the bend (usually referred to as microbend loss); changing the relative refractive indices of the core and the cladding of the optical fiber and thereby changing the guiding properties and again introducing a loss; modifying an optical phase delay by introducing a change in refractive index or a change in physical length; examining changes in birefringence introduced through modifications to physical stress and/or temperature; using external indicators to color modulate a broadband source and relate the color distribution to temperature, chemical activity, etc. These are all linear effects where the input optical frequency is the same as the output optical frequency (regarding Doppler shift as a rate of change of phase of an optical carrier) and where, for a given system setting, the output at all frequencies is directly proportional to the input.

Nonlinear effects are also widely exploited. Of these, the most important are fluorescence, observed usually in fluorophores external to the optical fiber, and Raman and Brillouin scattering, usually observed within the fiber itself. In all these phenomena, the light is absorbed within a material and re-emitted as a different optical wavelength from the one that was observed. The difference in optical wavelengths depends on the material and usually on strain and temperature fields to which the material is subjected. These major features of optical fiber sensors are encapsulated in Figure 32.84.
Optical fiber sensors have an additional feature that is unique to the medium — namely, the abilities for intrinsic networking in either distributed, quasi-distributed/multiplexed, or discrete (point) configurations. The essential features of these architectures are sketched in Figure 32.85. For intrinsic sensors, the fiber responds to the measurand throughout its length, and the output in transmission is an integral
of this linear response. However, using an interrogation scheme in reflection that incorporates a delay proportional to distance along the fiber enables the system to retrieve the measurand as a function of position. These are distributed sensors. The quasi-distributed architecture examines separately identified individual (usually adjacent) lengths of fiber and extracts the integral of the measurand along each of these individual lengths. Distributed and quasi-distributed sensors effectively convolve the measurand field along the interrogation fiber with a window determined by either the time resolution of the interrogating electronics (distributed architectures) or the defined lengths of the individual fiber sections (quasi-distributed systems).

Point and multiplexed systems address the measurement as essentially a point sample located at a specific distance along the interrogating fiber. All these architectures can realized in all optical fiber form and have been demonstrated to address a very wide range of measurements, often within a single network. The availability of distributed sensing is unique to optical fiber technology, as indeed are optical fiber-addressed passive arrays.

In summary, the optical fiber approach to measurement has the demonstrated capability to address a wide range of physical, chemical, and biological parameters. It must take its place along side other competing technologies against which its merits must be assessed. The principal benefits of using fiber optics include:

- Immunity to electromagnetic interference within the sensor system and within the optical feed and return leads
- The capacity for intrinsic distributed measurements
- Chemical passivity within the sensor system itself and inherent immunity to corrosion
- Small size, providing a physically, chemically, and electrically noninvasive measurement system
- Mechanical ruggedness and flexibility: optical fibers are exceptionally strong and elastic — they can withstand strains of several percent
- High temperature capability — silica melts at over 1500°C

There remain cost and user acceptability deterrents within the exploitation of optical fiber sensor technology. Consequently, the majority of field experience in optical fiber sensors is targeted at addressing the specialized problems where these aforementioned benefits are paramount. Many of these lie in the area of temperature measurement.

**Fiber Optic Temperature Sensors**

The important phenomena that have been exploited in the optical techniques for temperature measurement include:

- Collection and detection of blackbody radiation
- Changes in refractive index of external media with temperature
- Changes in fluorescence spectra and/or fluorescence rise times with temperature
- Changes in Raman or Brillouin scatter with temperature
- Phase transitions in carefully selected materials imposing mechanical modulation on optical fiber transmission properties
- Changes within an optical path length with temperature, either within the fiber or an external interferometer element

Within these phenomena, Brillouin and Raman scatter and mechanical phase transitions have been primarily used in distributed measurement systems. Some distributed measurement/quasi distributed measurement systems based on modulated to phase delay have also been evaluated, although they have yet to reach commercial reality. The remaining phenomena are almost exclusively used in point sensor systems.
Fiber Optic Point Temperature Measurement Systems

One of the first commercial optical fiber sensors was a fluorescence-based temperature probe introduced in the early 1980s by the Luxtron Corporation of Mountain View, CA. Successors to these early sensors are still commercially available and are a very effective, but expensive, approach to solving specific measurement problems. These include monitoring temperature profiles in both domestic and industrial microwave ovens, examining temperatures in power transformer oils, motor/generator windings, and similar areas where (primarily) the issue is the operation of a reasonably precise temperature probe within very high electromagnetic fields. In such circumstances, a metallic probe either distorts the electromagnetic field significantly (e.g., in microwave ovens) or is subjected to very high levels of interference, producing spurious readings. Other applications sectors exploit the small size or chemical passivity of the device, including operation within corrosive solvents or examination of extremely localized phenomena such as laser heating or in determining the selectivity of radiation and diathermy treatments.

The principles of the probe are quite simple and are shown in Figure 32.86. The rare earth phosphor is excited by an ultraviolet light source (which limits the length of the silica-based feed fiber to a few tens of meters) and the return spectrum is divided into “red” and “green” components, the intensity ratios of which are a simple single-valued function of phosphor temperature. For precision measurement, the detectors and feed fiber require calibration and, especially for the detectors, the calibration is a function of ambient temperature. However, this can be resolved through curve fitting and interrogation of a thermal reference. The instrument, which has now gone through several generations to improve upon the basic concept, is capable of accuracies of about ±0.1°C within subsecond integration times over a temperature range extending from approximately –50°C to ±200°C. Since its introduction, this particular

FIGURE 32.86 Optical fiber fluorescent thermometer.
The probe has accumulated extensive field experience in a wide variety of applications and remains among the most widely exploited fiber optic sensor concepts.

A number of temperature probes based on fluorescence decay time measurements have also been demonstrated. The level of commercial activity exploiting these concepts has, to date, been very modest, partly because the accurate measurement of decay times can be problematic.

Measuring the temperature response of dyes and other thermally sensitive color-selective materials can afford a very simple approach to temperature measurements. Among the most successful of these has been the temperature probe examining the bandedge of gallium arsenide introduced by ASEA (now ABB), again in the early 1980s and now transferred to Takaoka. The bandedge can either be monitored through examining the spectra of induced fluorescence or through interrogating the absorption characteristics of the material when subjected to a constant spectrum excitation. The accuracy and temperature range of this probe are comparable with those of the Luxtron system, and this particular version of the bandedge probe has the additional benefit of operating primarily in the near-infrared range of the spectrum, thereby accessing the best transmission characteristics of the optical fiber medium. The probe was originally conceived to address ASEA’s internal needs in monitoring electrical power system components. Similar bandedge probes have also been demonstrated based on absorption edge detection in materials such as ruby.

Refractometry and interferometry are potential extremely sensitive thermal probes. Several have been demonstrated, some of which achieve microkelvin resolution. Interferometric detection or exploitation of sensitive mode coupling phenomena is the source of this very high sensitivity, although rarely is such high sensitivity required in practice. The relatively simple Fabry Perot probe shown in Figure 32.87 has been introduced commercially with simplified spectral analysis and a semiconductor source, although as yet its market penetration has been relatively modest.

Optical pyrometry is a well-established approach to measuring temperatures in the hundreds to thousands of degrees Centigrade. The disappearing filament pyrometer has been used in this fashion for over half a century. The optical fiber equivalent has also found a few niche applications. The general
form of such a sensor is to place the black body at the end of the fiber and place it with the fiber into the hot zone. The consequent radiation within the transmission spectrum of the fiber is then monitored using a semiconductor photodetector that can be based on III-V materials or silicon. The received radiation is then primarily within the red and near-infrared from about 600 nm to, depending on the detector, 1.8 μm. Blackbodies radiate significantly in this range at temperatures in the hundreds of degrees Centigrade and above. The most significant success of this approach has been in the fabrication of the reference standard temperature probe at NIST for temperatures above 1200°C. This uses a sapphire rather than silica collection fiber because of its superior optical and thermal properties within the temperature and the wavelength ranges of interest. It defines these high temperatures with subdegree precision.

Optical fibers also have the capacity to make unique nanoprobes — the opposite end of the scale by orders of ten from the distributed sensors discussed below. These (Figure 32.88) are tapered optical fibers with the end reduced in diameter to tens of nanometers. The tapered region is coated with a metal, often aluminium or silver, to confine the optical field. This produces an intense spot of light at the fiber tip which irradiates an area nanometers in dimensions. The tip can be coated with the dye or the fluorescent thermally sensitive material and used to monitor temperature over extremely small areas. This enables thermal profiles within cellular dimensions to be assessed. In other formats, the same probe can also be used to address chemical activity and chemical composition.

Fiber optic temperature sensing can be realized using a wide variety of techniques primarily, but not exclusively, based on the variation of optical properties of materials with temperature. An example of the exceptions is the optical excited vibrating element probe shown in Figure 32.89. This probe has been primarily used for pressure measurement and is now available commercially for pressure assessment down-hole in oil wells. It can also be configured to exhibit extremely high temperature sensitivity with accuracies and resolutions in the millikelvin region. It uses the beneficial features of mechanical resonators and the consequential frequency read-out in parallel with optomechanical excitation and direct optical interrogation to produce a probe that can be reliably exploited over interrogation lengths of tens of kilometers.

Fiber optic point sensors for temperature measurement are now a relatively mature technology. Most of the devices mentioned above were first introduced and characterized 10 or more years ago and have since been refined to address specific applications sectors. They remain expensive, especially when compared to the ubiquitous thermocouple, but their unique capability for noninvasive electrically passive interference immune measurement give them a very specific market address that cannot be accessed using alternative technologies. Within these market areas, the probes have been extremely successful.

FIGURE 32.88 Probe for photon tunneling microscope and nano optrode.
Distributed and Quasi-distributed Optical Fiber Temperature Measurement Systems

These systems all exploit the unique capability for optical fibers to measure and resolve environmental parameters as a function of position along the fiber length. This generic technology is unique to optical fiber systems and, while there are a few commercial distributed temperature sensor systems available, the research in this sector continues.

The stimulated Raman scatter (SRS) distributed temperature probe is the most well established of these and, in common with many of the point sensors, was originally introduced commercially in the late 1980s. The principle (Figure 32.90) is quite simple. Within the Raman backscatter process (and also within the spontaneous Brillouin backscatter process), the amplitudes of the Stokes and anti-Stokes lines are related to the energy gap between these lines by a simple \( \exp(-\Delta E/kT) \) relationship. Therefore, measuring this ratio immediately produces the temperature. Furthermore, this ratio is uniquely related to temperature and cannot be interfered with by the influence of other external parameters. The system block diagram is shown in Figure 32.91. The currently available performance from such systems enables resolutions of around 1 K in integration times of the order of 1 min, with resolution lengths of one to a few meters over total interrogation lengths of kilometers. The interrogation can extend to tens of kilometers if either the interrogation times are increased or the temperature and/or spatial resolutions are relaxed. The system is available from both European and Japanese manufacturers. The applications are very specific, as indeed they must be to accommodate an instrument price that is typically in tens of thousands of dollars. The instruments have been used in a variety of highly specific areas, ranging from monitoring temperature profiles in long process ovens to observing the thermal characteristics within large volumes of concrete during the curing process.

Distributed temperature alarms triggering on and locating the presence of either hot or cold spots along the fiber can be realized at significantly lower costs and have been modestly successful as commercial systems. The first of these — and probably the simplest — was originally conceived in the 1970s. This uses a simple step index fiber in which the refractive index of the core material has a different temperature coefficient than that of the cladding material. The temperature coefficient is designed such that at a particular threshold temperature, the two indices become equal and thereafter that of the cladding exceeds that of the core. Within this section, light is no longer guided. Simple intensity transmittance measurement is then very sensitive to the occurrence of this threshold temperature at a particular point along the fiber. If used with an optical time domain reflectometer, the position at which this first event occurs can be located. This system is now in use as a temperature alarm on liquefied natural gas storage tanks. Here, the core and cladding indices for a plastic-clad silica fiber cross at a temperature in the region of
Such temperatures can only be achieved when a leak occurs. Further, the system has the obvious benefit of intrinsic safety and total compatibility with use within potentially explosive atmospheres.

A heat — as opposed to cold — alarm system that has also been introduced commercially is shown in Figure 32.92. In this system, the central tube is filled with a wax that expands by typically 20% when passing through its melting point. This expansion in turn forces the optical fiber against the helical...
binding, introducing a periodic microbend and thereby increasing the local loss within the fiber. The wax transition temperatures can be defined over a relatively wide range (say 30 to 70°C) and a low-cost OTDR system enables location of the hot spot to within a few meters. This system presents a very cost-effective over-heat or fire alarm when such systems are required and are in intrinsically safe areas or in regions of very high electromagnetic interference. Again, it is the unique properties of the optical fiber sensing medium — especially intrinsic safety and electromagnetic immunity — which provide this system with its market address.

Brillouin scatter is very similar in character to Raman scatter except that in Brillouin scatter the interaction is with an acoustic phonon rather than an optical phonon. The frequency shifts are then correspondingly significantly smaller (typically 10 to 15 GHz). Additionally in Brillouin scatter, the frequency of the scattered light depends on the acoustic velocities in the medium within which the light is scattering. Consequently, the Brillouin scatter spectrum is a function of both temperature (through variations of modulus and density) and strain applied to the optical fiber. Usually this is exploited as a complex but very effective means for measuring strain distributions along an optical fiber. The Brillouin scatter cross-section is much higher than that for Raman scatter so that distributed strain distributions can be measured over distances well in excess of 100 km. This measurement is particularly effective when exploiting stimulated Brillouin scatter that guides the scattered light back toward the source. However, since the apparent value of strain depends on temperature through the variation of acoustic velocity with temperature, temperature correction is required in most practical situations and, in principle, this correction can be implemented by measuring spontaneous Brillouin scatter and specifically the intensity ratio of this in the upper and lower sidebands. This particular correction technique is currently in its infancy, and accuracies in the degree kelvin range are the current state of the art. The difficulty in temperature measurement is that the energy gap between the two sidebands is very small so that the ratio of the amplitudes is close to unity but must be measured very accurately in order to invert the exponential.

The optical Kerr effect manifests itself as an intensity-dependent refractive index. Consequently, this nonlinearity gives rise to either second harmonic generation or sum and difference frequencies. It has been investigated for distributed temperature sensing using pump:probe configurations and birefringent fiber from which the beat length is a function of temperature and strain. This beat length in turn
determines the frequency offset through phase matching conditions of the mixed pump and probe signal (Figure 32.93). The overall situation is conceptually similar — this offset frequency depends on temperature and strain although in principle, dual measurements and adequate calibration can retrieve both, or alternatively the probe can measure a temperature field in the absence of strain. Again, the actual experimental results that have been achieved remain in the laboratory and the accuracies and resolutions are modest.

In quasi-distributed sensing and point multiplexed systems, temperature probes have, as yet, been but little exploited. There are many variations on the basic theme of a marked optical fiber within which the optical interrogation system measures the optical path length between the marks. These marks can be introduced using partially reflective gratings, mode coupling Bragg gratings, partially reflective splices or connectors, low reflectivity directional couplers, or a multitude of other arrangements. Similarly, the optical delay between the markings can be measured directly as an optical or subcarrier phase or indirectly through monitoring dispersion between adjacent modes typically in low moded or birefringent fibers. Yet again, the different delays depend on both temperature and strain so that for temperature measurement, a strain-free mounting is ideal. The context within which most, if not all, of this class of system has been evaluated is that of smart structures and here the technique does offer some promise as a means for deconvolving strain, mechanical, and thermal effects, and assessing structural integrity. It could also function as a temperature measurement probe, but to date has been minimally addressed in this application.

In multiple xed systems, the current fashion, again primarily for combined strain and temperature measurement, is to incorporate arrays of Bragg gratings used here as wavelength filters rather than as broadband reflectors. In this configuration, the Bragg grating presents a combined temperature/strain field at its location encoded within the reflection wavelength. Multiple addressing schemes can deconvolve temperature and strain sensitivities. There have also been a few demonstrations of discrete temperature-sensitive elements inserted at strategic points along an optical fiber. Of these the use of band edge shifting in ruby crystals interrogated using a pulsed source observed in reflection has probably been the most successful. In this arrangement, the reflectors are replaced by the crystals and sample the temperature field at these points. The receiver then determines the return to spectrum as a function of time.

**Applications for Optical Fiber Temperature Probes**

Instrumentation is a very applications-specific discipline and, in particular for sensors, a particular technology is usually only relevant in a limited number of application sectors. As the technology becomes more and more specialized and expensive, these applications niches become much more tightly defined.
For optical fiber sensors and their use in temperature probes, the more conventional approaches (thermocouples, thermisters, platinum resistance thermometers, etc.) are always easier and simpler. The fiber optic technology must exploit one or more of electromagnetic immunity, small size, noninvasiveness, chemical immunity, or the capacity for distributed measurement.

Point optical sensors are therefore primarily used as measurement probes in regions of very high electromagnetic fields, in zone zero intrinsically safe areas, and as *in vivo* medical probes.

The distributed capability of fiber sensors is especially relevant in structural monitoring and in other specialized areas such as measuring the temperature distribution along underground power lines, tunnels or similar structures or in experimental circumstances such as the measurement of curing processes in large volumes of concrete.

Fiber optics then is exactly similar to all other sensing techniques — it is an inappropriate temperature probe for the majority of applications; but for those for which it is appropriate, it offers a unique and effective solution to frequently otherwise intractable measurement challenges. As a technology evolves and becomes both more widely accepted and readily available, the applications address will no doubt expand.

**Further Information**

Additional information on optical fiber temperature measurements can be obtained from the following.

*International Conferences on Optical Fiber Sensors (OFS)* are regarded as the principal forum for the dissemination of research results OFS(1), London 1983 to OFS(12) Williamsburg, 1997, various publishers.

Thermal Conductivity Measurement

There are three mechanisms whereby energy can be transported from one region of space to another under the influence of a temperature difference. One is by transmission in the form of electromagnetic waves (radiation); the second is the process of convection, in which a bulk or local motion of the material effects the transport; and the final process is that of thermal conduction, when energy is transported through a medium. In most practical situations, energy transport is accomplished by all three processes to some extent, but the relative importance of each contribution varies markedly. For example, within an evacuated region, radiation is the sole mechanism of transport; whereas, in an opaque solid, conduction is the only mechanism possible.

These processes of heat transfer are often very important in a wide variety of scientific and industrial applications. In the cooling of cast or crystalline materials (e.g., metals, semiconductors, or polymers) from a molten state to a solid state, the heat transfer within the material can have a profound effect on the final properties of the solid. Equally, the heat transfer in a foodstuff is a determinant of its cooking, freezing, or processing time, while the size of equipment needed to heat or cool the liquid or gas stream in a chemical plant depends sensitively on the heat transfer within and between one stream and another.

For these reasons, there has been great interest in the understanding and description of all three heat transfer processes. Among the three, that of thermal conduction is the simplest to describe in principle, since the empirical law of Fourier simply states that the heat transported by conduction per unit area in a particular direction is proportional to the gradient of the temperature in that direction. The coefficient of proportionality in this law is known as the thermal conductivity and denoted here by the symbol \( \lambda \).

Many important materials, whether made of pure chemical components or mixtures, are of uniform composition throughout and for them the thermal conductivity is a true physical property of the material, depending often only on the temperature, pressure, and composition of the sample. However, particularly in the solid state, the thermal conductivity can depend on the direction of the heat flow, for example, in the case of a molecular crystal.

It is also conventional to speak of the thermal conductivity of various types of composite materials such as bricks, glass-fiber insulation, carbon-fiber composites, or polymer blends. In this case, the thermal conductivity is taken to be the empirical constant of proportionality in the linear relationship between a measured heat transport per unit area and the temperature difference over a prescribed distance in the material. The thermal conductivity is not then, strictly, a property of the material, since it can often
depend on a large number of parameters, including the history of the material, its method of manufacture, and even the character of its surface. However, this distinction between homogeneous and inhomogeneous materials is often ignored and leads to more than a little confusion, especially where intercomparisons among measurements are concerned.

The fact that in most practical situations all three heat transfer mechanisms are present greatly complicates the process of measurement of the thermal conductivity. Thus, much early work in the field is substantially in error, and it has been really quite difficult to devise methods of measurement that unequivocally determine the thermal conductivity. For that reason, the instruments to be described in the following sections often seem to be rather far removed from the apparent simplicity implied by Fourier’s Law.

33.1 Fundamental Equations

The essential constitutive equation for thermal conduction relates the heat flux in a material to the temperature gradient by the equation:

\[ Q = -\lambda \nabla T \quad (33.1) \]

It is not possible to measure local heat fluxes and gradients; thus, all experimental techniques must make use of an integrated form of the equation, subject to certain conditions at the boundaries of the sample. All experiments are designed so that the mathematical problem of the ideal model is reduced to an integral of the one-dimensional version of Equation 33.1, which yields, in general:

\[ Q_a = G \lambda \Delta T \quad (33.2) \]

in which \( G \) is constant for a given apparatus and depends on the geometric arrangement of the boundaries of the test sample. Typical arrangements of the apparatus, which have been employed in conjunction with Equation 33.2, are two flat, parallel plates on either side of a sample, concentric cylinders with the sample in the annulus and concentric spheres.

Techniques that make use of Equation 33.2 are known as steady-state techniques and they have found wide application, some of which are discussed below. They are operated usually by measuring the temperature difference \( \Delta T \) that is generated by the application of a measured heat input \( Q_a \) at one of the boundaries. The absolute determination of the thermal conductivity, \( \lambda \), of the sample contained between the boundaries then requires a knowledge of the geometry of the cell contained in the quantity \( G \). In practice, it is impossible to arrange an exactly one-dimensional heat flow in any finite sample so that great efforts have to be devoted to approaching these circumstances and then there must always be corrections to Equation 33.2 to account for departures from the ideal situation.

If the application of heat to one region of the test sample is made in some kind of time-dependent fashion, then the temporal response of the temperature in any region of the sample can be used to determine the thermal conductivity of the fluid. In these transient techniques, the fundamental differential equation that is important for the conduction process is:

\[ \rho C_p \frac{\partial T}{\partial t} = \nabla \cdot \left( \lambda \nabla T \right) \quad (33.3) \]

which arises from an elementary energy balance in the absence of any other processes and in which \( \rho \) is the density of the material and \( C_p \) its isobaric heat capacity. In most, but not all, circumstances, it is acceptable to ignore the temperature dependence of the thermal conductivity in this equation and to write:
in which \( a \) is known as the thermal diffusivity.

Experimental techniques for the measurement of the thermal conductivity based on Equation 33.4 generally take the form of the application of heat at one surface of the sample in a known time-dependent manner, followed by detection of the temperature change in the material at the same or a different location. In most applications, every effort is made to ensure that the heat conduction is unidirectional so that the integration of Equation 33.4 is straightforward. This is never accomplished in practice, so some corrections to the integrated form of Equation 33.4 are necessary. The techniques differ among each other by virtue of the method of generating the heating, of measuring the transient temperature rise, and of the geometric configuration. Interestingly, in one geometric configuration only, is it possible to determine the thermal conductivity essentially independently of a knowledge of \( \rho \) and \( C_p \), which has evident advantages. More usually, it is the thermal diffusivity, \( a \), that is the quantity measured directly, so that the evaluation of the thermal conductivity requires further, independent measurements.

In the following sections, brief descriptions of the specific applications of these general principles are given. The examples chosen for study are intended to cover the full spectrum of materials and thermodynamic states and, in each case, attention is concentrated on a method that has proved most accurate and is widely used. The steady-state and transient techniques are considered separately.

### 33.2 Measurement Techniques

#### Steady-State Methods

The steady-state methods employed for the measurement of the thermal conductivity of fluids and solids have most often employed the geometry of parallel plates so that it is that configuration described here in two variants. Coaxial cylinder equipment has largely been used within the preserve of the research laboratory, with the apparatus of Tufeu and Le Neindre [1] an excellent example of the genre.

**Parallel-Plate Instrument**

A schematic diagram of a guarded parallel-plate instrument is shown in Figure 33.1. The sample is contained in the gap between two plates (upper and lower) maintained a distance \( d \) apart by spacers. A small amount of heat, \( Q_a \), is generated electrically in the upper plate and is transported through the sample to the lower plate. Around the upper plate, and very close to it, is placed a guard plate. This plate is, in many instruments, maintained automatically at the same temperature as the upper plate so as to reduce heat losses from the upper surface of the upper plate and to most nearly secure a one-dimensional heat flow at the edges of the sample.

![Figure 33.1](image_url)

**FIGURE 33.1** Schematic diagram of a guarded parallel-plate instrument. (\( H = \) heater, \( R = \) resistance thermometer).
The temperatures at the surfaces of the upper and lower plates are measured very precisely, as is the electric input of energy, so that the thermal conductivity can, in principle, be evaluated from the equation:

\[ Q_a = \frac{A \lambda \Delta T}{d} \]  

(33.5)

where \( \Delta T \) is the measured temperature difference, and \( A \) is the area of the upper plate.

Whether the sample is a fluid or a solid, the electric energy generated in the upper plate is not all conducted to the lower plate. Thus, it is necessary in all cases to account for spurious heat losses and for all except opaque materials for the radiative transfer between the two surfaces. When the sample is transparent to radiation, this correction is straightforward and can be reduced by means of surface coating the plates to reduce their emissivity; but when the material absorbs radiation, the problem is much more complicated and has been the subject of some controversy in the past, which has since been resolved (p.147 of [2]). In many cases, the effort of performing absolute measurements cannot be justified so that the ratio \( A/d \) is determined by calibration with a material of known thermal conductivity.

**Measurement on Fluids**

Measurements with parallel-plate instruments on fluids have been performed for a considerable period of time. The technique has particular advantages in some special regions of thermodynamic space but requires great attention to detail if accurate results are to be obtained. In the most accurate instruments for fluids, the gap between upper and lower plates is kept as small as possible (perhaps as small as 0.2 mm). This has the benefit of reducing the effect of heat flows that are not normal to the heat surfaces, but more importantly the small gap contributes to the reduction of the heat transferred by bulk convective motion of the fluid. Indeed, if very small temperature differences are employed by heating the top plate (to have a stable density gradient) and considerable care is taken to align the parallel plates normal to the earth’s gravitational acceleration, then the effects of convective heat transfer can be rendered negligible (p.154 of [2]). It is a fact of history that the necessary care with this instrument has been taken by only a few workers so that despite the fact that the instrument has been used in the temperature range from 4 K to 800 K, and for pressures up to 250 MPa, only some of the measurements are reliable.

An example of what can be achieved with a parallel-plate instrument is provided by the work of Mostert [3] and Sakonidou [4] at the van der Waals laboratory in Amsterdam. They have used the technique near the critical point of a pure fluid or mixture where the extreme values of the compressibility make the fluid exceedingly prone to convection. In such circumstances, the small vertical extent of the fluid layer required for this technique avoids large density variations in the test layer and, combined with the fact that very small temperature differences (0.3 mK) can be employed, has enabled measurements of the thermal conductivity to be conducted to within 100 mK of the critical temperature at the critical density. Under these circumstances, the thermal conductivity of a pure fluid reveals an enhancement that is, in principle, infinite at the critical point itself.

The unique characteristics of the parallel-plate instrument mean that it is the method of choice for work near the critical region of a material. The arguments above pertaining to the care required for reliable measurements militate against the production of commercial instruments.

**Measurements on Solids**

A parallel-plate instrument of exactly the same type as has been described for fluids has been employed for solids. However, the spacing of the two plates is normally significantly greater for solids, owing to the difficulty of preparing very thin samples of solids. One essential difficulty with solid samples in this configuration is the contact between the two heater surfaces and those of the sample. Unlike the case for fluids, the contact cannot be made uniform at the molecular level. There is therefore always the possibility of an unaccounted interfacial heat transfer resistance. It seems likely that these considerations contribute to the wide differences between values reported for the same sample by different authors.
A more popular implementation of the parallel-plate configuration for solids is the so-called heat flow-meter instrument. When applied to materials such as building insulation, the dimensions of this type of instrument can be very large.

In such instruments (see Figure 33.2), the upper heater plate is set at a higher temperature than the lower one. The hot and cold surface temperatures of the sample are measured with the two thermocouples permanently installed on the adjacent surface plates, while a precalibrated heat flow transducer on the lower plate measures the magnitude of the heat flux through the sample. The thermal conductivity is calculated directly from Equation 33.5. In some cases, contact resistances (i.e., insulation) can be characterized and controlled by employing a pressurized gas in the sample chamber. Commercial instruments of this type are included in the listing of Table 33.1.

**Transient Methods**

There are rather more transient techniques that have achieved popularity than steady-state instruments. This is because transient techniques generally require much less precise alignment and dimensional knowledge and stability. Furthermore, some of the techniques have distinct advantages that arise from the speed of the measurement. Here we have space to describe only one technique in detail which has, in a variety of ways, far greater applicability.

Transient Hot-Wire Technique

In this technique, the thermal conductivity of a material is determined by observing the temporal evolution of the temperature of a very thin metallic wire (see Figure 33.3) after a step change in voltage has been applied to it. The voltage applied results in the creation of a line source of nearly constant heat flux in the fluid. As the wire is surrounded by the sample material, this produces a temperature field in the material that increases with time. The wire itself acts as the temperature sensor and, from its resistance change, its temperature change is evaluated and this is related to the thermal conductivity of the surrounding material.

According to the ideal model of this instrument, an infinitely long, line source of heat possessing zero heat capacity and infinite thermal conductivity is immersed in an infinite isotropic material, with physical properties independent of temperature and in thermodynamic equilibrium with the line source at time \( t = 0 \) at a temperature \( T_0 \). The heat transferred from the line source to the sample when a stepwise heat flux, \( q \), per unit length is applied, is assumed to be entirely conductive. Then the temperature rise of the material at a radial distance, \( r_0 \), which it transpires, is the same as the temperature rise at the surface of a wire of radius \( r_0 \), is \( \Delta T_i(r_0, t) \) is given by:

\[
\Delta T_i(r_0, t) = T(r_0, t) - T_0 = \frac{q}{4\pi \lambda} \left[ \ln \left( \frac{4at}{r_0^2 C} \right) + \frac{r_0^2}{4at} + \cdots \right]
\]  

(33.6)

In the above equation, \( C \) is a known constant [5]. The equation suggests that, provided the radius of the wire is chosen small enough so that the second term on the right-hand side of Equation 33.6 is negligible, the thermal conductivity of the fluid can be obtained from the slope of the line \( \Delta T_i \) vs. \( \ln t \). Any practical implementation of this method of measurement inevitably deviates from this ideal model. The success of the technique, however, rests on the fact that by proper design, it is possible to construct an instrument that can operate very closely to the ideal model, while at the same time small departures can be treated by a first-order analysis [5].

The transient hot-wire technique was first developed in the 1930s to measure the effective thermal conductivity of powders. However, its application to other materials was somewhat slower until in the late 1960s the new technology associated with electronics made it possible to measure small, transient resistance changes with high accuracy in a period of less than 1 s. This development, pioneered by Haarman [6], made it possible to complete the transient heating process so quickly that, despite the inevitability of convective motion in the fluid from time zero, the inertia of the fluid ensures that the fluid velocity is sufficiently small that there is no significant contribution to heat transfer. This fact prompted a rapid development of the measurement technique for fluids — first in gases and then in liquids — that was then followed by further developments in solids. The differences in the technique
between solids and fluids are rather small; thus, some aspects of the instrumentation for liquids are briefly discussed and the differences for solids are just outlined.

In the case of fluids, the instrumentation generally involves a wire some 7 μm to 25 μm in diameter (in order to reduce the correction owing to its heat capacity) and some 150 mm long. The wire is mounted vertically in a cylindrical cell containing the test sample. Often, a second wire differing only in length is employed to compensate automatically for effects at the ends of the wires via the electrical measurement system, but this can also be accomplished with potential taps [5]. Whenever possible, platinum is used for the wire material because its resistance/temperature characteristics are well known and it can be readily obtained in the form of wires with a diameter as small as 5 μm. When the material under test is electrically conducting, it is necessary to insulate electrically the wire from the fluid. A variety of techniques have been employed for this purpose that enjoy different degrees of success depending on the range of conditions to be studied. Near ambient temperature over a range of pressures, it has been found adequate to use a tantalum wire as the sensor that is electrolytically anodized to cover the wire with an insulating layer of tantalum pentoxide 100 nm thick [7]. Under more aggressive conditions, it has been necessary to employ ion-plating of the wire with a ceramic to secure the isolation [8]. In either case, the theory has been modified by the addition of a small correction.

In the case of solids, the need for the wire to be straight and vertical is removed by virtue of the rigidity of the material. Thus, Bäckström and colleagues [9] were able to employ a wire embedded as an arc within the compressed solid matrix of the material under study, particularly at very high pressures (up to 4 GPa).

The transient hot-wire technique has a unique advantage among transient methods that the thermal conductivity of the test material can be evaluated directly from the slope of the line relating the temperature rise of the wire to the logarithm of time. The heat capacity and density of the test material are required only to evaluate small corrections. Furthermore, the exact dimensions of the heating element and the cell are also unimportant so that the method avoids the intricate alignment problems of the parallel-plate technique while securing absolute measurements of the property. Despite these advantages and its wide application to measurements in gases, solids, and liquids, there has been no commercial development of an instrument of this kind, presumably because of the delicacy of the long, thin wire in the case of devices for fluids, and the difficulty of sample preparation for solids.

**Hot-Disk Instrument**

A transient technique for which there is a commercial version suitable for solid materials is the transient hot-disk instrument shown in Figure 33.4.

The sensor in this case comprises a thin metal strip, often of nickel, wound in the form of a double-spiral in a plane. It is printed on, and embedded within, a thin sandwich formed by two layers of a material that is a poor electric conductor but a good thermal conductor. This disk heater is then, in turn, placed either between two halves of a disk-shaped sample of solid material or affixed to the outside of the sample.

![FIGURE 33.4 Schematic diagram of a transient hot-disk instrument.](image)
However it is configured, the essential measurement performed is the same as that for the hot-wire technique, and the temperature history of the sensor when subject to known electrical dissipation is inferred from its resistance change. In the most recent version of the instrument, developed by Gustafsson [10], and also available commercially, the interpretation of the data is accomplished via a numerical solution of the differential equation rather than by some analytical approximation to it. The technique is used frequently for studies of polymer composites, glasses, superconductors, and insulating materials.

**Heated-Needle Probe**

A further commercial device exists for the measurement of the thermal conductivity of granular materials such as powders and soils, natural materials such as rock and concrete and, indeed, of food. The probe is shown schematically in Figure 33.5 where it is seen that it consists of a thin, hollow, metallic needle (diameter 3 mm) containing an electric heater and a separate thermistor as a probe of the temperature history of the needle following initiation of a heat pulse [11]. The temperature history of the probe is generally interpreted with the aid of the equation appropriate to a transient hot-wire instrument but in a relative manner whereby its response is calibrated against known standards. This rather simplistic approach to the analysis of a somewhat complex cell inevitably restricts the accuracy that can be achieved, but does provide a measurement capability where no other technique is viable. It is often employed for measurements in inhomogeneous samples such as rocks or soils where it is simply the effective thermal conductivity that is required.

**Laser-flash Instrument**

A final transient technique is that which has become known as the laser-flash technique developed originally for measurements in solids but occasionally used on liquids, particularly at high temperatures.

Figure 33.6 contains a schematic diagram of the instrument as it is available today in a commercial form. The sample is illuminated on one face with a laser pulse of very short duration and high intensity. The absorption of the laser energy on the front face of the sample causes the generation of heat at that front surface, which is subsequently transmitted throughout the sample to the back face of the sample where the temperature rise is detected with an infrared remote sensor. The interpretation of measurements is based on a one-dimensional solution of Equation 33.4 subject to an initial condition of an instantaneous heat pulse at one location.

![Heated-Needle Probe](image-url)
The temperature rise at the back face of a sample of thickness $l$ and radius $r$, is therefore given by [12]:

$$ \Delta T(l,t) = \frac{Q}{\rho C_p l \pi r^2} \left[ 1 + 2 \sum_{n=1}^{\infty} \left(-1\right)^n \exp \left( -\frac{n^2 \pi^2 at}{l^2} \right) \right] $$

(33.7)

where $Q$ is the energy absorbed at the front surface at time zero. The thermal diffusivity of the sample, $a$, is then often deduced from the measurement of the time taken for the back face of the sample to reach one half of its maximum value. The technique has the very distinct advantage that it does not require physical contact between the test sample and the heater or detector. For this reason, it is a particularly appropriate technique for use at high temperatures or in aggressive environments.

However, there are a number of precautions that must be taken to ensure accurate results. First, the theory should be modified to account for non-unidirectional heat flow. Secondly, care must be taken to ensure that no radiation incident on the front face penetrates to the back face for transparent samples. Due care must also be taken to match the laser power to the system being studied so that there is neither fusion nor ablation at the front face that can distort the results. Finally, when the fluid state is studied, due care should be taken to eliminate convective heat transport. Seldom are all of these precautions adopted in routine work, so that some results obtained with the technique are of dubious validity. Nevertheless, the method has seen widespread application to a wide range of materials, including composites, polymers, glasses, metals, refracting materials, insulating solids, and coatings.

Finally, the radial heat-flow method should also be mentioned. This is a transient technique in which the sample is heated and cooled continuously [13]. From the recording of the temperature gradient via thermocouples, the thermal diffusivity is obtained and thus the thermal conductivity is calculated. The advantage of the radial heat-flow method is that the measurements are fast and only small temperature gradients are necessary in the sample. A commercially available instrument operating according to this technique is listed in Table 33.1.

### 33.3 Instrumentation

Table 33.1 lists various instruments for the measurement of the thermal conductivity of solids, while the addresses of the suppliers are shown in Table 33.2. As already mentioned, to our knowledge, there is no company that produces instruments specifically for the measurement of the thermal conductivity of fluids.

### 33.4 Appraisal

Naturally, the technique to be employed for the measurement of thermal conductivity depends on the type of sample to be studied and the range of conditions to be employed. For fluid samples under most conditions, a variant of the transient hot-wire method must be the preferred technique. Under favorable

---

© 1999 by CRC Press LLC
conditions, an accuracy of ±0.3% can be achieved and a level of ±1% is possible under all but the most aggressive circumstances. Near the critical region of fluids, a parallel-plate instrument is essentially the only viable method. For molten materials at high temperature, while a variant of the hot-wire system has advantages, the laser-flash technique is very attractive but an accuracy of no better than 10% is then to be expected.

For solids, the hot-disk or laser-flash techniques have many features that recommend them when the sample is amenable to appropriate preparation. In those cases, an accuracy of a few percent should be possible but is rarely attained. For samples such as rocks, the heated needle-probe is undoubtedly the only viable technique.

It should be emphasized again here that when a sample is inhomogeneous, the quantity determined is not the thermal conductivity of any element of it, but rather an effective value suitable for engineering purposes. It is not an intrinsic thermophysical property of the material.

References

Thermal management of materials and processes is becoming a sophisticated science in modern society. It has become accepted that living spaces should be heated and cooled for maximum comfort of the occupants. Many industrial manufacturing processes require tight temperature control of material throughout processing to establish the desired properties and quality control. Examples include control of thermal stresses in ceramics and thin films, plasma deposition, annealing of glass and metals, heat treatment of many materials, fiber spinning of plastics, film drying, growth of electronic films and crystals, and laser surface processing.

Temperature control of materials requires that energy be transferred to or from solids and fluids in a known and controlled manner. Consequently, the proper design of equipment such as dryers, heat exchangers, boilers, condensers, and heat pipes becomes crucial. The constant drive toward higher power densities in electronic, propulsion, and electric generation equipment continually pushes the limits of the associated cooling systems.

Although the measurement of temperature is common and well accepted, the measurement of heat flux is often given little consideration. Temperature is one of the fundamental properties of a substance. Moreover, because temperature can be determined by human senses, most people are familiar with its meaning. Conversely, heat flux is a derived quantity that is not easily sensed. It is not enough, however, to only measure the temperature in most thermal systems. How and where the thermal energy goes is often equally or more important than the temperature. For example, the temperature of human skin can indicate the comfort level of the person, but has little connection with the energy being dissipated to the surroundings, particularly if evaporation is occurring simultaneously. Wind chill factor is another common example of the importance of convection heat transfer in addition to air temperature.

Maximizing or minimizing the thermal energy transfer in many systems is crucial to their optimum performance. Consequently, sensors that can be used to directly sense heat flux can be extremely important. The subsequent material in this chapter is intended to help individuals understand and implement heat flux measurements that are best suited for the required applications.
34.1 Heat Transfer Fundamentals

The movement of thermal energy is known as “heat” and the rate of this transfer is commonly called “heat transfer.” It is given the symbol \( q \) and has the units of watts. The heat transfer per unit area is termed the “heat flux” and is given the symbol \( \dot{q} \) with the units of \( \text{W m}^{-2} \). Although in some cases only the overall heat transfer from a system is required, often the spatial and temporal variation of the heat flux is important to performance enhancement. Methods for measuring the spatial or temporal distribution of heat flux are identified and discussed in this chapter. Detailed simultaneous measurements of both spatial and temporal distributions of heat flux, however, are generally not feasible at this time.

One of the most important principles concerning heat transfer is the first law of thermodynamics, which states that the overall energy transfer to and from a system is conserved. It includes all types of energy transfer across the system boundary, including the three modes of heat transfer — conduction, convection, and radiation. For the simple example shown in Figure 34.1, the transient energy balance on the control volume marked can be expressed as:

\[
mC \frac{dT}{dt} = a_{\text{convection}} + q_{\text{radiation}} - a_{\text{conduction}}
\]

where \( m \) is the mass of the system and \( C \) is the corresponding specific heat. The effect of the thermal capacitance \((mC)\) of the material causes a time lag in the temperature response of the material to a change in heat transfer. A short summary of important heat transfer principles follows, with many engineering textbooks available in the field that give additional details.

Conduction

Conduction encompasses heat transfer through stationary materials by electrons and phonons. It is related to the temperature distribution by Fourier’s law, which states that the heat flux vector is proportional to and in the opposite direction of the temperature gradient:

\[
\dot{q} = -k \nabla T
\]

The constant \( k \) is the thermal conductivity of the material. Measuring this temperature gradient is one of the basic methods for determining heat flux.

For a homogeneous material in Cartesian coordinates Equation 34.1 becomes:

\[
\frac{\partial T}{\partial t} = a \left( \frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} \right)
\]
where \( a \) is the thermal diffusivity of the material with a density of \( \rho \), \( a = k/(\rho C) \). Measuring the temperature response of the system according to this equation is the second major method for determining the heat transfer. Because of the complexity of solutions to Equation 34.3, this method can be complicated if multidimensional effects are present.

If steady-state one-dimensional heat transfer can be assumed throughout the planar solid in Figure 34.1, the temperature distribution in the direction of heat flux \( q'' \) is linear. Equation 34.2 becomes simply:

\[
q'' = k \frac{T_i - T_s}{\delta}
\]  

(34.4)

where the temperatures are specified on either side of the material of thickness \( \delta \).

As illustrated in Figure 34.1, convection and radiation are the other modes of heat transfer typically present at the surface of a solid. These are usually the quantities of interest to measure with a heat flux sensor. Both are present at least to some extent in virtually all cases, although the effects of one or the other are often purposely minimized to isolate the effects of the other.

**Convection**

Although heat transfer by convection occurs by the same physical mechanisms as conduction, the fluid is free or forced to move relative to the surface. The fluid motion greatly complicates the analysis by coupling the heat transfer problem with the fluid mechanics. Particularly when the flow is turbulent, the fluid equations are generally impossible to solve exactly. Consequently, the heat transfer and fluid mechanics are commonly isolated by introduction of a heat transfer coefficient, which encompasses all of the fluid flow effects.

\[
q'' = h_r \left( T_r - T_i \right)
\]  

(34.5)

The temperature of the fluid is represented by \( T_r \), which for low-speed flows is simply the fluid temperature away from the surface. The recovery temperature is used for high-speed flows because it includes the effect of frictional heating in the fluid. The subscript \( r \) on the heat transfer coefficient, \( h_r \), implies that the boundary condition on the surface is a constant temperature, \( T_r \). Although other surface temperature conditions can be encountered, it is then important to carefully document the surface temperature distribution because it can have a profound effect on the values of \( h \) and \( q'' \) [1, 2].

**Radiation**

Heat transfer by radiation occurs by the electromagnetic emission and adsorption of photons. Because this does not rely on a medium for transmission of the energy, radiation is very different from conduction and convection. Radiation has a spectrum of wavelengths dependent on the temperature and characteristics of the emitting surface material. Moreover, the surface properties are often dependent on the wavelength and angular direction of the radiation. One classic example is material that looks black to the visible spectrum, but is transparent to the longer wavelengths of the infrared spectrum. Consequently, special coatings are sometimes applied to surfaces to control the absorption characteristics. For example, the surface of a radiation sensor is often coated with a high absorptivity paint or graphite.

Because the power emitted from a surface is proportional to the fourth power of the absolute temperature, radiation detectors are usually cooled sufficiently for the power emitted from the detector itself to be negligible. In this case, the temperature distribution of the sensor is not important. This is a big advantage over convection measurements where the temperature distribution on the surface has a big influence on the measurement.
34.2 Heat Flux Measurement

Most of the many methods for measuring heat flux are based on temperature measurements on the surface or close to the surface of a solid material. Usually this involves insertion of a device either onto or into the surface, which has the potential to cause both a physical disruption and a thermal disruption of the surface. As with any good sensor design, the goal for good measurements must be to minimize the disruption caused by the presence of the sensor. It is particularly important to understand the thermal disruption caused by the sensor because it cannot be readily visualized and because all heat flux sensors have a temperature change associated with the measurement. Consequently, wise selection of the sensor type and operating range is important for good heat flux measurements. The following sections emphasize important factors in using the currently available heat flux sensors, followed by short summaries of sensors used in research and possible future developments. They are grouped by the general type of sensor action.

34.3 Sensors Based on Spatial Temperature Gradient

The heat flux at the material surface can be found at a location if the temperature gradient can be determined at that position, as indicated in Equation 34.2. Because it is difficult to position temperature sensors with the requisite accuracy inside the material, sensors to measure heat flux are either applied on the surface or mounted in a hole in the material. In the following sections, the different types of commercially available sensors are discussed first and listed in a table by manufacturer. Shorter sections briefly describing sensors used in research labs or currently being developed follow.

One-Dimensional Planar Sensors

The simplest heat flux sensor in concept is illustrated in Figure 34.2. The one-dimensional heat flux perpendicular to the surface is found directly from Equation 34.4 for steady-state conditions:

\[ q'' = \frac{k}{\delta} (T_1 - T_2) \]  

(34.6)

The thickness of the sensor \( \delta \) and thermal conductivity \( k \) are not known with sufficient accuracy for any particular sensor to preclude direct calibrations of each sensor. An adhesive layer may also be required between the sensor and surface to securely attach the sensor, which adds an additional thermal resistance.
and increases the thermal disruption. Temperature measurements on the sensor and on the surrounding undisturbed material are recommended to quantify this disruption. Although the temperature difference can be measured by any number of methods, the most commonly used are thermocouples. Thermocouples have the advantage that they generate their own voltage output corresponding to the temperature difference between two junctions. Consequently, they can be connected in series to form a thermopile that amplifies the output from a given temperature difference. An illustration of a thermopile for measuring a temperature difference is given in Figure 34.3. Most any pair of conductors (e.g., copper–constantan) can be used for the legs of the thermopile, but the output leads should be of the same material so that additional thermocouple junctions are not created. The voltage output, $E$, is simply:

$$E = NS_1(T_1 - T_2)$$  \hspace{1cm} (34.7)

where $N$ represents the number of thermocouple junction pairs, and $S_1$ is the Seebeck coefficient or thermo electric sensitivity of the materials, expressed in volts per degree Centigrade. The corresponding sensitivity of the heat flux sensor is:

$$S = \frac{E}{q'} = \frac{NS_1 \delta}{k}$$  \hspace{1cm} (34.8)

Although the sensitivity is determined in practice from a direct calibration, the last part of the equation can be used to determine the effects of different parameters for design purposes.

One successful design using a thermopile was described by Ortolano and Hines [3] and is currently manufactured by RdF Corp., as listed in Table 34.1. Thin pieces of two types of metal foil are alternately wrapped around a thin plastic (Kapton) sheet and butt-welded on either side to form thermocouple junctions, as illustrated in Figure 34.4. A separate thermocouple is included to provide a measure of the sensor temperature. The flexible, micro-foil sensors are 75 $\mu$m to 400 $\mu$m thick and can be glued to a variety of surface shapes, but are limited to temperatures below (250°C) and heat fluxes less than 100 kW m$^{-2}$. This covers many general-purpose industrial and research applications. The time response can be as fast as 20 ms, but transient signals can be attenuated unless the frequency of the disturbance is less than a few hertz. First-order systems, such as these sensors, give 70% response to a sinusoidal input with a period six times the exponential time constant.

FIGURE 34.3 Thermopile for differential temperature measurement [2].
A similar design uses welded wire to form the thermopile across a sensor about 1 mm thick. This gives a higher sensitivity to heat flux, but also a larger thermal resistance. Time constants are on the order of 1 s and the upper temperature limit is 300°C. These are manufactured in a range of sizes by International Thermal Instrument Co., as listed in Table 34.1. Applications include heat transfer in buildings and physiology. Sensors with higher sensitivity are made with semiconductor thermocouple materials for geothermal applications. Lower sensitivity sensors are made for operating temperatures up to 1250°C.

A much thinner thermopile sensor called the Heat Flux Microsensor (HFM) was described by Hager et al. [4] and is manufactured by Vatell Corp., as listed in Table 34.1. Because it is made with thin-film sputtering techniques, the entire sensor is less than 2-μm thick. The thermal resistance layer of silicon monoxide is also sputtered directly onto the surface. The resulting physical and thermal disruption of the surface due to the presence of the sensor is extremely small. Use of high-temperature thermocouple materials allows sensor operating temperatures to exceed 800°C for the high-temperature models. They are best suited for heat flux values above 1 kW m⁻², with no practical upper limit. Because the sensor is so thin, the thermal response time is less than 10 μs [5], giving a good frequency response well above 1 kHz. A temperature measurement that is integrated into the sensor is very useful for checking the heat

**FIGURE 34.4** Thermopile heat flux sensor [3].
flux calibration [6] and determining the heat transfer coefficient. The high temperature and fast time response capabilities are useful for aerodynamic applications, combusting flows in engines and propulsion systems, and capturing high-speed events such as shock passage.

Terrell [7] describes a similar sensor design made with screen printing techniques of conductive inks. A copper/nickel thermocouple pair was used with a dielectric ink for the thermal resistance layer. The inks were printed onto anodized aluminum shim stock for the substrate. Although the entire package is 350-μm thick, the thermal resistance is low because of the high thermal conductivity of all of the materials. These are currently offered commercially by Vatel Corp., as listed in Table 34.1. Because of the large number of thermocouple pairs (up to 10,000), sensitivities are sufficient to measure heat fluxes as low as 0.1 W m⁻². The thermal time constant is about 1 s, and the upper temperature limit is approximately 150°C. The aluminum base allows some limited conformance to a surface. Applications include the low heat fluxes typical of building structures, biomedicine, and fire detection.

Another technique for measuring the temperature difference across the thermal resistance layer is to wrap wire and then plate one side of it with a different metal. A common combination is constantan wire with copper plating. The resulting wire-wound sensor looks similar to the sensor shown in Figure 34.4. The difference is that the constantan wire is continuous all around the sensor, so it does not form discrete thermocouple junctions. A summary of the theory is given by Hauser [8] and a general review is given by van der Graaf [9]. Concept Engineering offers a range of these type of sensors at moderate cost. Because of the hundreds of windings on these sensors around 2-mm thick plastic strips, the sensitivity to heat flux is high. The corresponding thermal resistance is also large and time constants are around 1 s. Temperatures are limited to about 150°C. Thermonetics also makes a plated wire-wound heat flux sensor. Thicknesses range from 0.5 mm to 3 mm, with time constants greater than 20 s. Some of the units are flexible and can be wrapped around objects. The normal temperature limit is 200°C, but ceramic units are available for operation above 1000°C. The main use for these sensors is to measure heat flux levels less than 1 kW m⁻², with applications including building structures, insulation, geothermal, and medicine.

One popular version of plated wire sensors uses a small anodized piece of aluminum potted into a circular housing, commonly known as a Schmidt-Boelter gage. Kidd [10] has performed extensive analyses on these gages to determine the effect of the potting on the measured heat flux. Neumann [11] discusses applications in aerodynamic testing. The sensors are commercially available from Medtherm Corp. in sizes as small as 1.5-mm diameter. There is also some ability to contour the surface of the sensor to match a curved model surface for complex test article shapes.

Circular Foil Gages

The circular foil or Gardon gage consists of a hollow cylinder of one thermocouple material with a thin foil of a second thermocouple material attached to one end. A wire of the first material is attached to the center of the foil to complete a differential thermocouple pair between the center and edge of the foil as illustrated in Figure 34.5. The body and wire are commonly made of copper with the foil made of constantan. Heat flux to the gage causes a radial temperature distribution along the foil as illustrated in Figure 34.5. The circular foil gage was originated by Robert Gardon [12] to measure radiation heat transfer. For a uniform heat flux typical of incoming radiation the center to edge temperature difference is proportional to the heat flux (neglecting heat losses down the center wire):

\[ T_o - T_i = q'R^2 \left( \frac{1}{4k\delta} \right) \]  

The thickness of the foil is δ and the active radius of the foil is R. The temperature difference produced from center to edge of the foil is measured by a single thermocouple pair, typically copper-constantan. The output voltage is proportional to the product of the temperature difference in Equation 34.9 and the thermoelectric sensitivity of the differential thermocouple.
These sensors are reasonably rugged and simple. They are manufactured by two companies at moderate cost (Medtherm and Vatell), and are often used as secondary standards for measurement of radiation. One important application is the measurement of the heat flux occurring during fire tests to check flammability of materials. The biggest problems with the circular foil gages arise when they are used with any type of convection heat transfer. It has been shown analytically and experimentally that the output is incorrect for convective heat transfer because of the distortion of the temperature profile in the foil from the assumed radially symmetric, parabolic profile of radiation [13]. Because the amount of error is a function of the gage geometry, the fluid flow, and the heat transfer coefficient, it is difficult to reliably correct. The errors become particularly large when the sensor is used in a flow that has a shear flow component [14], which encompasses most convection situations. Consequently, great care must be used to keep the temperature difference across the gage $T_o - T_i$ small if Gardon gages are used to measure convective heat transfer.

When the gages are used in high heat flux situations, such as combustors, water cooling is usually supplied through the body of the sensor to keep the temperature from exceeding material limits. Because of the resulting temperature mismatch of the gage and surrounding material in which it is mounted, a water-cooled gage is not recommended for convection heat transfer measurements. It is also important for a water-cooled gage to ensure that condensation does not occur on the sensor face. Although most heat flux sensors are designed to measure the total heat flux, sensors have been developed to separate convection from radiation. The most common method is to put a transparent window over the sensor to eliminate convection to the sensor face. Because the resulting sensor only measures radiation, it is termed a radiometer. The field of view is limited, however, in these radiometers and must be included in the interpretation of results. In a dirty environment where the transmission of the window could be degraded, air is blown across the face of the window to keep the particles away from the sensor. Both manufacturers of the circular foil gages (Medtherm and Vatell) make these radiometer versions. Applications include use in high-ash boilers and gas turbine combustors.

**Research Sensors**

Although not commercially available, heat flux sensors using RTDs (resistance temperature devices) have been developed to measure the required temperature difference across a heat flux sensor. They are not as convenient for measuring small temperature differences as thermocouples, however, because RTDs require two individual temperature readings to be subtracted. Conversely, a thermocouple pair reads the temperature difference between the two junctions directly and allows the formation of thermopiles with many pairs of junctions to amplify the signal.
Researchers at MIT have developed a sensor like the Micro-Foil thermopile sensor using a nickel resistance element on each side of the plastic sheet [15]. One advantage of knowing the individual temperatures rather than the temperature difference is that the time response of the sensor can be analytically enhanced up to 100 kHz with appropriate modeling. Hayashi et al. [16] used vacuum deposition to create thin-film heat flux sensors like the HFM sputtered thermopile sensors except using a nickel RTD on either side of the silicon monoxide thermal resistance layer. The frequency response was estimated from shock-tunnel experiments to be 600 Hz.

Future Developments

The most exciting recent advances in the field of heat flux measurement have been provided by thin-film technology. Continued improvements in size, sensitivity, price, and time response are anticipated. As the size of sensors continues to decrease, the deposition of thin-film heat flux sensors directly on parts as they are manufactured should become a reality.

34.4 Sensors Based on Temperature Change with Time

Equations 34.1 to 34.3 give the form of the relationship between the unsteady response of temperature and surface heat transfer. If the thermal properties of the wall material are known along with sufficient detail about the temperature history and distribution, the heat transfer as a function of time can, in principle, be determined. Although temperature sensors are available from manufacturers, the necessary data manipulation must be done by the user to obtain heat flux. There are two types of solutions used to reduce the temperature history to heat flux. These are discussed separately as the semi-infinite solution and calorimeter methods. In addition, a variety of methods for measuring the required temperature history are discussed.

Semi-Infinite Surface Temperature Methods

An important technique for short-duration heat flux tests is to measure the surface temperature history on a test object with a fast-response temperature sensor. For short enough times and sufficiently thick material, it can be assumed that the transfer is one-dimensional and that the thermal effects do not reach the back surface of the material. Equation 34.3 reduces to a one-dimensional, semi-infinite solution, which is simple to implement for this case. For example, the surface temperature for a step change of heat flux at time zero is

\[
T_s - T_i = \frac{2q''\sqrt{t}}{\sqrt{\pi\kappa\rho C}}
\]

(34.10)

The substrate properties are the thermal conductivity, density, and specific heat, represented by the product \(\kappa\rho C\). \(T_i\) is the uniform initial temperature of the substrate and \(T_s\) is the surface temperature as a function of time.

A good criteria for the time limit on the test is the time before 1% error occurs in the heat flux [17]:

\[
t = 0.3\frac{L^2}{a}
\]

(34.11)

Here, \(a\) represents the thermal diffusivity of the substrate material and \(L\) is the substrate thickness. For a typical ceramic substrate (MACOR), the corresponding minimum thickness for 1 s of test time is 1.6 mm. High conductivity materials, such as metals, have much larger required thicknesses.

Data analysis of the measured temperature record can be performed by several methods. The simplest is to use the analytical solution with each sampled data point to recreate the heat flux signal. The most
The popular equation for this conversion is that attributed to Cook and Felderman [18] for uniformly sampled data:

\[
q'(t_n) = 2\sqrt{\pi \Delta t} \sum_{j=1}^{n} \frac{T_j - T_{j+1}}{\sqrt{n-j} + \sqrt{n+1-j}}
\]

This can easily be implemented for digital data with a short computer program to perform the summation for the measured points. Modifications are also available to provide more solution stability [17]. More complex techniques include the use of parameter estimation techniques [19] and numerical solutions to account for changes in property values with the changing temperature [20]. Because of the noise amplification inherent in the conversion from temperature to heat flux, analog methods have been developed to convert the temperature signal electronically before digitizing the signal [21].

There are many methods for measuring surface temperature that can be used to determine heat flux. Two broad categories are point measurements using thermocouples or RTDs and optical methods that allow for simultaneous measurement of temperatures over the entire surface. They all require substantial effort from the user to initiate the test procedure and reduce the data to find heat flux. Places for additional information and a few sources for temperature sensors are given.

Point temperature measurements for determining convective heat flux are often made with thin-film RTDs. A metallic resistance layer is sputtered, painted and baked, or plated onto the surface. Because the resulting thickness of the sensor is less than 0.1 µm, the response time is a fraction of 1 µs and there should be no physical or thermal disruption of the measured temperature due to the sensor. Most researchers develop techniques for instrumenting models themselves. Transient flow facilities provide an easy method for quickly initiating the flow and heat transfer, as required by this transient method. However, the model can also be injected into the flow or the flow can be quickly diverted to provide the fast initiation of heat flux. The method is used for basic measurements applicable to gas turbine engines, rockets, internal combustion engines, and high-speed aerodynamics [2].

A special type of thermocouple is made for surface temperature measurement, called coaxial thermocouples [22]. It has one thermocouple wire inside the second thermocouple material with an insulating layer in between. One end is mounted into a metal sheath for press fitting into the surface material for testing. A thin thermocouple is formed by combining the two metals right at the end of the assembly. Response times are typically 1 ms or less, which although slower than the thin-film sensors is sufficient for most applications [11]. The cost per sensor is moderate and they are available from Medtherm Corp., as listed in Table 34.1.

A new approach to measure the transient surface temperature at a point is being developed using a fiber optic probe embedded in the surface [23]. A Fabry-Perot interferometer is the basis for the technique, which has the advantages of high spatial resolution and no electrical connections.

Null-point calorimeters [24] are a further extension of the semi-infinite surface temperature method. They are designed for measurement of extremely high levels of heat flux (over 1000 kW m⁻²). To protect the thermocouple and wires, they are mounted in a cavity behind the surface. The geometry of the null-point calorimeter is designed, however, for the thermocouple to measure a temperature that would match the surface temperature of a semi-infinite material so that Equation 34.14 can be used for data reduction [24]. Medtherm is the current supplier of null-point calorimeters, as indicated in Table 34.1.

Optical methods give the opportunity to measure the entire temperature field over a section of the surface. Consequently, much data can be collected over each test, but interpretation to obtain quantitative heat flux values is more challenging than measurements with point sensors. The visual display of the temperature over the surface can be very qualitatively informative, however.

The most popular optical method for measuring temperature is to record the color change using liquid crystals. These are specially prepared molecules that reversibly change their color reflection through several distinct colors as a function of temperature, typically in the range of 25°C to 40°C. The best for transient measurements are the chiral-nematic form that have been microencapsulated to stabilize their properties. A variety of types can be obtained from Hallcrest (in Table 34.1), which can be used over the...
temperature range from 5°C to 150°C. They can easily be spray-painted onto a blackened surface for testing. Setting the lighting for reproducible color, temperature calibration, image acquisition, and accurately establishing the starting temperature are crucial steps. Detailed procedures for accurate measurements have been established by several groups [25–28]. The basic materials are cheap, but the associated equipment is expensive. As listed in Table 34.1, Image Therm Engineering offers a complete system for temperature measurement, including a high-quality video camera, lighting system, calibration system, computer hardware and software for image processing, and a liquid crystal kit.

As previously discussed for radiation heat transfer, all surfaces emit radiation with an intensity and wavelength distribution that can be related to the surface temperature. The advent of high-speed infrared scanning radiometers has made it feasible to record the transient temperature field for determination of the heat flux distribution [29]. A coating is usually applied to establish a known, high absorptivity surface. To convert the measured radiation emission to surface temperature, the radiation field of the surroundings is also required. The camera and associated equipment are quite expensive.

Thermographic phosphors emit radiation in the visible spectrum when illuminated with ultraviolet light. The intensity of emission at specific wavelengths can be related to the temperature over a wide range of surface temperatures. The potential high-temperature applications are particularly appealing [30]. A CCD camera is required to record the transient optical images and calibration is challenging.

**Calorimeter Methods**

A calorimeter is a device for measuring the amount of absorbed thermal energy. The slug calorimeter [31] assumes that the temperature throughout the sensor is uniform while it changes with time. When exposed to a fluid at a temperature $T_r$ and heat transfer coefficient $h$ over an active area of $A$, the solution for the temperature change is simply an exponential:

$$\frac{T - T_i}{T_r - T_i} = e^{-t/\tau} \tag{34.13}$$

where $T_i$ is the initial temperature and the time constant is:

$$\tau = \frac{mC}{hA} \tag{34.14}$$

with the active surface area represented by $A$. The thermal capacitance is the product of the mass of the sensor and the specific heat. The time constant can be found from the temperature response of the system, which can then be used in Equation 34.14 to quantify the heat transfer coefficient, $h$. Although these calorimeters are simple in principle, it is often difficult to obtain reliable results because of heat losses and nonuniform temperatures.

A more useful device, called the plug-type heat flux gage, was developed by Liebert [32] at NASA Lewis. An annulus is created on the backside of the surface by electrical discharge machining. Four thermocouples are attached along the remaining plug to estimate both the temperature gradient and the change in thermal energy content in the plug. This gives a better estimate of the heat flux than the slug calorimeter. An additional advantage is that the measurement surface is physically undisturbed.

Another calorimeter technique, called the thin skin method, uses the entire test article as the sensor. Models are constructed of thin metals and instrumented with thermocouples on the back surface. The temperature is assumed constant throughout the material at any location, but varies with time and position around the model. The main errors to be avoided are: (1) lateral conduction along the surface material, (2) heat loss by conduction down the thermocouple wires, and (3) heat loss from the back surface, which is usually considered adiabatic. Because of the recent advances in thin-film and optical surface temperature measurement, the thin-skin method is considered outdated for most modern aerodynamic testing [11].
34.5 Measurements Based on Surface Heating

For research on convective heat transfer, electric heating provides an easy method of controlling and measuring the heat flux to the surface. A combination of guard heaters and proper insulation allows control of the heat losses to give an accurate knowledge of the heat flux leaving the surface based on the total electrical power supplied once steady-state conditions have been established. The temperature of the surface and fluid are used in Equation 34.5 to give the heat transfer coefficient for the surface:

\[ h = \frac{q''}{T_s - T_r} \]  (34.15)

As with the transient temperature methods, it requires considerable experimental design and expertise by the user to begin making measurements.

34.6 Calibration and Problems to Avoid

Calibration of heat flux is a complicated issue because some heat flux sensors respond to different modes and conditions of heat flux differently. For example, a sensor calibrated by radiation can have a substantially different response to the same amount of heat flux in convection. For the low heat fluxes seen in building applications, the guarded hot-plate method has been well established [33]. The National Institute of Standards and Technology (NIST) maintains calibration devices for this range of conduction heat transfer. Calibrated insulation samples are readily available to check other guarded hot-plate calibrators. Calibration of sensors at elevated temperatures has demonstrated that there is a dependence of the heat flux sensitivity on sensor temperature [34].

There have been several important advances in heat flux calibration for more general industrial applications within the past few years. NIST is completing three heat flux calibration facilities. A blackbody radiation facility operating to 100 kW m⁻², a laminar flow convection facility, and a helium conduction facility are currently being completed and tested [35–37]. This combination of facilities will allow comparison of sensor response under the different modes of heat transfer. In addition, Arnold Engineering Development Center (AEDC) has recently acquired a radiation calibration facility for elevated sensor temperatures (up to 800°C). The temperature dependence of the heat flux sensitivity is thought to be substantial for many sensors. Because in the past most all calibrations have only been performed with the sensors at room temperature, this is an important new facility.

As with many other measurements, the major problem with heat flux measurement is the error caused in the heat flux by the disruption of the sensor itself. For sensors based on the spatial temperature gradient methods, a larger signal implies a larger temperature difference and a larger temperature disruption. For the second type of sensors based on the transient temperature change, the surface temperature is changing while the measurement occurs. The larger the temperature change, the easier the determination of the sensor heat flux, but the larger the error from the sensor temperature disruption.

The error caused by the thermal disruption of the sensor can be estimated for conduction [38]. In convection, however, the effect of the surface temperature disruption on the developing thermal boundary layer is much more difficult to estimate and the effect on the heat flux can be much larger than the percentage change of the temperature [2]. Therefore, it is imperative in convection measurements to keep the thermal disruption of the sensor to a minimum.

34.7 Summary

There are a large number of off-the-shelf heat flux sensors available. Those commercially available have been listed in Table 34.1, and the information for contacting the manufacturers is given in Table 34.2.
The differential temperature devices provide a direct readout of the heat flux over the surface of the sensor. With the proper choice of sensor for the application and care in measurement method, the results are easily interpreted and used. Alternatively, the transient temperature methods can provide more surface details, but the output is a surface temperature history that must be analyzed to obtain the corresponding heat flux. Although certain components of these systems are off-the-shelf, more work is required of the user to interpret the results. Issues of calibration and errors have been addressed briefly here. More detail on all aspects of heat flux measurement can be obtained from the manufacturers and the references listed.

References

All objects at temperatures above absolute zero emit electromagnetic radiation. Radiation thermometry makes use of this fact to estimate the temperatures of objects by measuring the radiated energy from selected regions. Thermal imaging takes the process one stage further and uses the emitted radiation to generate a picture of the object and its surroundings, usually on a TV display or computer monitor, in such a way that the desired temperature information is easily interpreted by the user.

Thermal imagers require no form of illumination to operate, and the military significance of this, together with their ability to penetrate most forms of smoke, has been largely responsible for driving thermal imager development. Although thermal imagers intended for military or security applications can be used for temperature measurement, they are not optimized for this purpose since the aim is to detect, recognize, or identify targets at long ranges by their shape; thus, resolution and sensitivity are favored over radiometric accuracy.

### 35.1 Essential Components

All thermal imagers must have a detector or array of detectors sensitive to radiation in the required waveband, and optics to form an image of the object on the detector. In modern thermal imagers, the detector array might have a sufficient number of sensitive elements to cover the focal plane completely (a “staring array”), in the same way as a CCD television camera. Some of the most recent staring arrays can give good performance without cooling. In other imagers, the detector might take the form of a single row or column of elements, in which case a scanning mechanism is required to sweep the image across the detector array. If a single-element detector, or a very small detector array, is used, a means of...
providing a two-dimensional scan is required. (Figure 35.1 shows these options schematically.) For scanning imagers, it is necessary to cool the detectors (usually to about 80 K to 120 K) to achieve adequate performance.

Although in principle it would be possible to deduce target temperature from the absolute value of the detector signal, it is necessary in practice to estimate temperature by comparison with one or more reference bodies of known temperature. The temperature references are usually internal to the equipment, and accessed by mechanical movement of the reference (which may take the form of a rotating chopper) or by deflecting the optical path using a mirror.

### 35.2 Thermal Imaging Wavebands

The optimum waveband for thermal imaging is determined partly by the wavelength distribution of the emitted radiation, partly by the transmission of the atmosphere, and partly by the chosen detector technology.

The power radiated from a given area of an object depends only on its temperature and the nature of its surface. If the surface absorbs radiation of all wavelengths completely, it is referred to as a “blackbody.” It then also emits the maximum amount possible, which can be calculated using the Planck equation (given later). Figure 35.2(a) shows the way in which blackbody emission varies with wavelength for several temperatures. It will be seen that for objects near normal ambient temperature, maximum output occurs at a wavelength of about 10 μm, or about 20 times the wavelength of visible light. At wavelengths below about 3 μm, there is generally insufficient energy emitted to allow thermal imaging of room-temperature objects. The emissivity at any wavelength is defined as the ratio of the energy emitted at that wavelength to the energy that would be emitted by a blackbody at the same wavelength.

It is important that the atmosphere should have sufficient transparency to permit the target to be observed. There are two important “atmospheric windows”—one between 3 μm and 5 μm (with a notch at 4.2 μm due to carbon dioxide absorption) and one between 7.5 μm and 14 μm. These are commonly...
referred to as the medium-wave infrared (MWIR) and long-wave infrared (LWIR) windows, respectively. For thermal measurement over short ranges in the laboratory, it is possible to work outside these bands, but most instruments are optimized for either the MWIR or LWIR. Typical transmissions through 1 km and 10 m of a clear U.S. Standard Atmosphere are shown in Figures 35.2(b) and 35.2(c).

Emissivity for most naturally occurring objects and organic paints is high (>0.8) in the LWIR, but is lower and more variable in the MWIR. Solar radiation in the MWIR is significant, and can cause errors in measurements made outdoors. These considerations favor the LWIR for quantitative imaging, but the band chosen can also be influenced by the chosen detector technology, the latter frequently being determined by cost. Scanning imagers can be used in either band, but are more sensitive for a given detector architecture in the LWIR. Cooled staring arrays give similar sensitivity in either band, but are currently more readily available in the MWIR. Uncooled staring arrays work well only in the LWIR band.

For temperature measurement, the electronics can be used to encode signal level as false color, a color scale derived from the thermal references being injected into the display to allow the user to identify the temperature of the object under examination. For general surveillance, a conventional gray-scale image
is usually preferred. Imagers for thermography can also include emissivity compensation. If accurate results are required for an object of low emissivity, it is important to ensure that the temperature of anything that might be reflected by the object is known and that the emissivity is accurately known. If the object is accessible, another object placed beside it with the same surface characteristics but known temperature can be used for calibration.

35.3 Emission from Source

The spectral radiance \( W(\lambda, T) \) of a blackbody at temperature \( T \) and wavelength \( \lambda \) is given by the Planck equation [1]. For temperature differences between the target and the reference of a few degrees, it is frequently sufficiently accurate to assume a linear dependence of radiance on temperature difference, making the temperature derivative of the blackbody equation, \( dW(\lambda, T)/dT \), more relevant. In the case of photon detectors, the detector output is proportional to the photon flux, which can be derived from the radiance using the fact that photon energy \( E(\lambda) = h\nu/\lambda \), where \( h \) is the Planck constant. The total photon flux \( N(\lambda) \) and its derivative with respect to temperature are thus relevant in this case. The equations are as follows:

\[
W(\lambda, T) = \frac{c_1}{\lambda^2} \left( \frac{c_2}{e^{c_2/T} - 1} \right), \quad \text{W m}^{-2} \mu\text{m}^{-1} \tag{35.1}
\]

\[
N(\lambda, T) = \frac{c_3}{\lambda^3} \left( \frac{c_2}{e^{c_2/T} - 1} \right), \quad \text{photons s}^{-1} \text{m}^{-2} \mu\text{m}^{-1} \tag{35.2}
\]

\[
\frac{dW(\lambda, T)}{dT} = \frac{c_1 c_2 e^{c_2/T}}{\lambda^4 T^2} \left( \frac{c_2}{e^{c_2/T} - 1} \right), \quad \text{W m}^{-2} \mu\text{m}^{-1} \text{K}^{-1} \tag{35.3}
\]

\[
\frac{dN(\lambda, T)}{dT} = \frac{c_1 c_2 e^{c_2/T}}{\lambda^5 T^3} \left( \frac{c_2}{e^{c_2/T} - 1} \right), \quad \text{photons s}^{-1} \text{m}^{-2} \mu\text{m}^{-1} \text{K}^{-1} \tag{35.4}
\]

where: Numerical values of the constants are:

\[
c_1 = 3.742 \times 10^8
\]

\[
c_2 = 1.439 \times 10^4
\]

\[
c_3 = 1.884 \times 10^{27}
\]

The unit of wavelength is chosen for convenience to be the micrometer (\( \mu\text{m} \)).

The above values are for radiation into a hemisphere. The intensities (watts per steradian, photons per steradian, etc.) are obtained by dividing the above values by \( \pi \). The actual radiances for real targets are obtained by multiplying by the spectral emissivity \( \varepsilon(\lambda) \); but since target reflectivity \( \rho(\lambda) = 1 - \varepsilon(\lambda) \), some caution is required. For example, a target at temperature \( T \) surrounded by a background of temperature \( T_b \) will appear to emit \( W(\lambda, T)\varepsilon(\lambda) + W(\lambda, T_b)\rho(\lambda) = [W(\lambda, T) - W(\lambda, T_b)]\varepsilon(\lambda) + W(\lambda, T_b) \).
Provided that the background surrounds the target and that the target is reasonably small, the background acts as an isothermal enclosure, which can be shown [2] to behave as an ideal blackbody (i.e., \( \varepsilon(\lambda) = 1 \)).

The differential spectral radiance against background \( \Delta W(\lambda) \) is thus \( (W(\lambda, T) - W(\lambda, T_b))\varepsilon(\lambda) \), which for a small temperature difference \( \Delta T \) is simply:

\[
\Delta W(\lambda) = \varepsilon(\lambda) \frac{dW(\lambda, T)}{dT} \Delta T
\]

The spectral emissivity of a wide variety of natural and man-made objects is also given in [2].

A major difference between thermal imaging and visual imaging is the very low contrast. In the MWIR, the contrast calculated from Equation 35.1 due to 1 K at the target is about 4%, falling to about 2% in the LWIR.

### 35.4 Atmospheric Transmission

Provided that the absorption bands shown in Figures 35.2(b) and 35.2(c) are avoided, atmospheric transmission can frequently be ignored in the laboratory or industrial context. For longer ranges, an atmospheric transmission model must be used or calibrating sources must be placed at the target range.

The standard atmospheric transmission model is LOWTRAN [3], currently at version 7. The atmospheric transmission \( T_a(\lambda) \) reduces the differential signal from the target proportionately, but has no effect on the background flux if the atmosphere is at background temperature. Atmospheric transmission in the LWIR is severely affected by high humidity, making the MWIR the band of choice for long-range operation in the Tropics. (Many gases and vapors such as methane or ammonia have very strong absorptions in the infrared, making thermal imaging a possible means of leak detection and location.)

### 35.5 Detectors

There are two main types of detector — photon (or quantum) and thermal. A more detailed discussion of photon detectors is given in this handbook in Chapter 8.1.1 and 8.1.2, and of thermal detectors in Chapter 6.1.8, so only aspects unique to thermal imaging are discussed here.

**Photon Detectors**

In photon detectors, the response is caused by photons of radiation that generate free carriers in a semiconductor, which in turn increase the conductivity (for photoconductive detectors) or generate a potential difference across a junction (for photovoltaic detectors). Photovoltaic devices have the advantage of not requiring a bias current (important to reduce the heat load on the cooling system), and they have 40% lower noise because the electric field at the junction separates the carriers, thereby eliminating recombination noise. Whether or not the lower noise is achieved in practice depends on the read-out electronics. The photon energy in the LWIR is only about \( 1/20^{th} \) of that of a photon in the visible region of the spectrum, so a semiconductor with a much smaller bandgap than silicon must be used. The most widely used material is a compound of mercury, cadmium, and tellurium (MCT or CMT) since not only is the quantum efficiency excellent (70% or more), but the bandgap can be tuned to the desired wavelength (in either waveband) by altering the composition. Cooling of the detector to about 80 K is desirable for the LWIR, but about 120 K is acceptable for the MWIR. For the MWIR, indium antimonide (InSb) is also an excellent material; and since it is a true stoichiometric compound, it is easier to achieve good uniformity of response, but cooling to 80 K is required.

Detectors for use in scanning systems are frequently arranged so that several elements are scanned over the same part of the scene in rapid succession, the output of each element being delayed and added
to the previous one to enhance the signal-to-noise ratio (SNR). This approach (Figure 35.3) is termed serial scanning or “time-delay and integrate” (TDI) mode, and gives a theoretical gain in the SNR equal to the square root of the number of elements in TDI. It is also possible to perform TDI in the detector material itself. In the SPRITE detector (Signal Processing In The Element), the sensitive element is an elongated strip of CMT. Photons incident on the device generate carriers that drift toward a read-out electrode near one end. If the image is scanned along the detector at the same speed as the carrier drift, the signal builds up along the length of the device. The useful length is limited by carrier recombination, while diffusion of the carriers limits spatial resolution.

Large arrays of photon detectors are generally of hybrid construction, the sensitive elements being bonded to a silicon CCD or CMOS addressing circuit using indium “bumps” (Figure 35.4). An exception is the Schottky barrier detector (e.g., platinum silicide), which can be manufactured by a monolithic process, and thus tends to be lower in cost, but quantum efficiency is much lower and operation is usually limited to the MWIR band. Detector arrays and read-out architectures are discussed in depth in [2] Vol. 3, p. 246-341 and [4].

The detector assembly is encapsulated in a Dewar as shown in Figure 35.5. In front of the detector is a “cold shield” that limits the acceptance angle of the radiation to match that of the optics.
Thermal Detectors

Thermal detectors rely on the heating effect of the incoming radiation, the change in temperature causing a change in resistance, capacitance, or electrical polarization that might be detected electrically. They are generally fairly slow in response (several milliseconds) but have the advantage that cooling is not essential (although it can be of considerable benefit with some types). The detectivity of uncooled thermal detectors is typically 1/100 that of cooled photon detectors, so real-time imaging requires the use of staring arrays. The essentials of a pyroelectric array are shown in Figure 35.6. Incoming radiation is absorbed by the blackened electrode, and the heat generated is transferred to the pyroelectric layer, which comprises a dielectric material that has been polarized by means of a high electric field during manufacture. The change in electrical polarization with temperature gives the electric signal. One of the most important parameters is the thermal isolation of the sensitive elements, so some kind of insulating support structure is necessary; and for good performance, the device must be evacuated to prevent convection. In a variant of this approach, the dielectric bolometer, the rapid variation of the dielectric constant at temperatures near the Curie point, causes the capacitance of the sensitive element to change, and hence the voltage for a constant charge. A detailed description of this approach is given in [5]. In both techniques, the detector responds only to change in temperature, so it is necessary to modulate the incoming radiation using a chopper. In the technique used initially by Wood [6] (now licensed to several manufacturers), the sensitive elements are vanadium dioxide coatings that undergo a large change in resistivity for a small temperature change. The elements are supported by silicon strips that are micromachined from the substrate and give excellent thermal insulation of the element. Changes in resistivity are read out by circuitry on the substrate, and no chopping is required, but the array must be maintained at a precise and uniform temperature.

Detector Performance Measures

The wavelength-dependent power responsivity of a detector $R(\lambda)$ is defined as the output potential or current that would result from 1 W of radiation at wavelength $\lambda$, assuming that linearity was maintained at such a high flux level. The units are V W$^{-1}$ or A W$^{-1}$. Photon responsivities in V photon$^{-1}$ s$^{-1}$ and A photon$^{-1}$ s$^{-1}$ are similarly defined.
A thermal detector has a power responsivity that is essentially independent of wavelength, the limits of response being determined by the transparency of the window and the absorption spectrum of the element or the material used to blacken it.

In an ideal photon detector, the quantum efficiency $\eta$ (defined as the number of carriers generated per photon) would be constant at all wavelengths for which the photon energy is greater than the bandgap, i.e., the photon responsivity is independent of wavelength up to the chosen cut-off wavelength. Since a given number of Watts corresponds to a number of photons proportional to the wavelength, the power responsivity (V W$^{-1}$ or A W$^{-1}$) would increase linearly with wavelength until the cut-off. In practice, the cut-off is spread over about 0.5 μm and shortwave performance is modified by window transmission and antireflection coatings.

The sensitivity of a detector is limited by noise that may be due to the detector itself or due to the background radiation (as is discussed later). Noise-equivalent power NEP($\lambda$) is defined as the power incident on the detector at wavelength $\lambda$, which gives a signal equal to the rms noise when the measurement is made with a 1-Hz bandwidth. The NEP depends also on the modulation frequency, the latter effect being large for thermal detectors, but frequently negligible for quantum detectors. For many types of detector, the noise is proportional to the square root of the sensitive area $A_d$ and the electrical bandwidth $B$, so that $\sqrt{(A_dB)/\text{NEP}(\lambda)}$ is constant. A performance figure that is proportional to sensitivity can then be defined as specific detectivity $D^*(\lambda) = \sqrt{(A_dB)/\text{NEP}(\lambda)}$. For historical reasons, specific detectivity is usually given in units of cm$\sqrt{\text{Hz W}}^{-1}$, so it is important to remember to convert this to SI units or to measure detector area in square centimeters. Since noise is an electrical quantity particular to the detector under the conditions for which $D^*$ is defined and is independent of wavelength, NEP($\lambda$) is proportional to $1/R(\lambda)$; so if the value of detectivity $D^*_p$ at the wavelength of peak responsivity $R_p$ is known, for other wavelengths $D^*(\lambda) = D^*_p(R(\lambda)/R_p)$. Sometimes, “blackbody $D^*(T)$” figures are quoted rather than $D^*_p$. If the blackbody temperature is $T$, the value of $D^*_p$ is given by:

$$D^*_p = \frac{D^*(T)R_p\int_0^\infty W(\lambda,T)d\lambda}{\int_0^\infty W(\lambda,T)R(\lambda)d\lambda}$$

(35.6)
The rms noise voltage $V_n$ is simply the NEP multiplied by the responsivity. Since the ratio $D^*(\lambda)/R(\lambda)$ is independent of wavelength, one obtains:

$$V_n = \sqrt{A_0 BR_p \frac{R}{D_p}}$$  \hspace{1cm} (35.7)

The detector also affects the modulation transfer function (MTF) of the imager, defined as the ratio of the modulation depth of the signal due to a target with sinusoidally varying brightness of spatial frequency $f$ cycles per milliradian to the modulation depth from a similar target at very low frequency. If there are no limitations due to time constant, the MTF of a detector is due to its instantaneous field of view (IFOV), which is given by $\text{IFOV} = \pi fF$ where $F$ is the focal length of the optics. For example, a lens of 500-mm focal length used with a 50-µm square detector would give an IFOV of 0.1 mrad. Then,

$$\text{MTF}_d = \frac{\sin(\pi f \times \text{IFOV})}{\pi f \times \text{IFOV}}$$  \hspace{1cm} (35.8)

For staring arrays, frequencies above 1/2 cycle per element pitch (the Nyquist frequency) give aliasing, and it is undesirable to rely on performance above this frequency.

**Detector Cooling**

The method with the lowest cost is to use liquid nitrogen poured directly into the detector Dewar, and many detector manufacturers supply detectors in Dewars with sufficient capacity for many hours of use per filling. Outside the laboratory, this technique is seldom practical, and a cooling engine (usually based on the Stirling thermodynamic cycle) is commonly used. The cost of such an engine has now fallen to a level where it no longer dominates the cost of the instrument, and power consumption is only a few watts to give cooling to 80 K. Dimensions vary widely, but a typical low-power cooling engine is about 40 mm × 40 mm × 60 mm excluding the length of the cold finger that lies inside the detector Dewar. A disadvantage is the relatively slow cool-down time (several minutes typically) and, where this is critical (as in military or security applications), Joule-Thomson cooling can be used. This method operates by expansion of air or nitrogen compressed to about 15 MPa through a nozzle, and can give cool-down times of a few seconds. Thermoelectric cooling (using the Peltier effect) can be used for temperatures down to about 200 K. Some detectors (e.g., lead selenide) have been designed to operate at this temperature in the 3 µm to 5 µm band, but thermoelectric cooling is inadequate for most types of photon detectors. A survey of cooling methods and devices is given in [2], Vol. 3, p. 345–431.

**35.6 Electronics**

The electronics architecture depends on the type of detector and the application, but typically electronics are required to provide bias and clocking signals to the detector, to amplify the low-level signals from the detector, to equalize the responses of the outputs from different detector elements, to provide scan conversion to a form suitable for display, and to provide image processing suitable to the application.

In scanning imagers with a small number of detector elements, the output of each detector element can be amplified continuously, the amplifier outputs then being multiplexed to give the required display. The bandwidth (important for estimating sensitivity) must be at least sufficient to accommodate the data rate, but too wide a bandwidth gives excess high-frequency noise. An approach frequently used for the measurement of sensitivity (e.g., [1], p. 167) is to make the electronics response equivalent to that of a single-pole filter with the 3-dB point placed at a frequency corresponding to $1/(2 \times \text{dwell time})$, in which case the bandwidth is:

© 1999 by CRC Press LLC
where \( \text{FOV}_h \) and \( \text{FOV}_v \) = Horizontal and vertical fields of view, respectively

\[ f = \text{Field rate} \]

\[ E = \text{Ratio of the active scan period to the total period} \]

\[ N = \text{Number of parallel detector channels} \]

Often high-frequency boost filters are used to compensate for optics and detector MTFs, in which case the noise bandwidth can be much increased. A commonly used criterion for the electronic filtering is to make the perceived noise independent of frequency up to the cut-off frequency of the detector.

To maintain good spatial resolution, it is desirable that the detector output be sampled at least twice during the dwell time so that the Nyquist frequency is not a major limitation \cite{7}. Frequencies above the Nyquist frequency are changed by the sampling process into lower frequencies, a process known as aliasing. Thus, the fidelity of the image is affected so that noise that might be expected to be of sufficiently high frequency to be filtered out can appear within the passband. To avoid aliasing, a steep-cut filter is used to eliminate frequencies above the Nyquist frequency before sampling. In staring systems, the Nyquist sampling frequency is 1/2 cycle per element pitch, so a 256 × 256 element array would be limited to a resolution of 128 cycles per line. This can be overcome by using “microscan” (or mscan), in which the image is collected over a number of fields with an image shift performed optically between each field, the commonest patterns being diagonal (low implementation cost) and 2 × 2 with four fields per frame.

For large detector arrays, charge is usually accumulated on a capacitor associated with each pixel for an integration time \( \tau \) (which can often be controlled independently of the frame rate or dwell time to prevent saturation), the capacitor being discharged when the pixel is read out. The effective bandwidth of such an integrator is:

\[ B = \frac{1}{2\tau} \]  

With state-of-the-art amplifiers, it is generally possible to make amplifier and read-out noise less than the detector noise, the exceptions being systems of small aperture that are “photon starved” and uncooled systems.

In multichannel systems, a crucial role of the electronics is to provide channel equalization. The importance of this is due to the very low contrast of the target against the background. If the full sensitivity of an imager with a typical NETD of 0.1 K is to be realized, the difference in response between adjacent detector channels must be less than 0.4% in the MWIR or 0.2% in the LWIR. In a real-time imager where the eye integrates over several frames, the requirement is 2 to 3 times more stringent, since nonuniformity, unlike signal-to-noise ratio, is not improved by eye integration.

### 35.7 Optics and Scanning

The materials commonly used for visual optics are opaque in the thermal wavebands. In the LWIR, germanium is by far the most widely used material. It has a refractive index of 4, and chromatic dispersion is sufficiently low that it is frequently unnecessary to use a second material for color correction. These properties allow high performance to be achieved with few optical components, largely offsetting the relatively high cost of the material. In the MWIR, germanium has fairly high dispersion, but silicon/germanium doublets give highly achromatic performance. Zinc selenide and zinc sulfide are commonly used for color correction, some forms of the latter being transparent also in the visible band. The high refractive indices make anti-reflection coating essential to reduce surface losses — the transmission of a thin piece
of uncoated germanium is only 40%, rising to better than 99% when coated. Front-surface mirrors coated with aluminum or gold perform well in the thermal bands, and optics based on parabolic mirrors can be used if the detector array is small. For most applications, it is necessary to seal the imager to prevent ingress of dust or moisture, in which case a window is required, making reflecting optics less attractive than it first appears, since the cost of a mirror and window can be a little less than that of a lens. Plastic materials in general have poor transmission, although a thin polythene or “cling-wrap” window might be acceptable for laboratory use.

For uncooled staring arrays, the sole function of the optics is to focus an image of the scene on the detector. Good performance in the 8 μm to 12 μm band can be achieved with a two-element Petzval lens [8] with aspheric surfaces (Figure 35.7(a)). With a cooled array, it is desirable that the cold shield inside the detector should form the aperture stop of the system, since any radiation from the interior of the instrument will add to the system noise and might give shading effects. If the field of view is reasonably small, it is sometimes possible to use the same type of lens in the manner shown in Figure 35.7(b), but it can be seen that the beam diameter that can be accepted is now much smaller than the lens diameter; thus, for long-range applications requiring large beam diameters, the lens becomes very costly. The solution is to use re-imaging optics as shown in simplified form in Figure 35.7(c). The relay stage not only re-images the scene on the detector, but images the cold shield on the objective lens so that the latter need be no larger than the input beam. The intermediate image can be useful to allow insertion of temperature references or microscanning.

Scanning, when required, is most commonly performed by moving reflective surfaces since electro-optic and acousto-optic techniques either provide insufficient deflection angle or are highly wavelength dependent, causing smearing over the thermal wavebands. Rotating refractive polygons are now less used than previously. For fast line scanners, rotating reflective polygons (sometimes with curved facets) are
used, in some cases using gas-bearing motors operating in helium to reduce windage. For frame scanning, a plane mirror driven by a powerful galvanometer is customary. This can give very linear sweeps at 60 Hz with scan efficiencies of about 80% when operated in a closed loop. For microscan or interlace, a small image movement can be achieved by tilting a mirror using piezoelectric actuators or by tilting a refractive plate using a galvanometer. For scanning systems, it is generally necessary to re-image the detector cold shield at each scan mechanism, since otherwise the optics must be enlarged to accommodate pupil movements. Figure 35.8 shows how this is done in a typical imager using a linear array. The movement of the interlace mirror is sufficiently small that pupil re-imaging at this mirror is not required.

Figure 35.9 shows a typical arrangement for a 2-D scanner, a high-speed polygon rotor being used to generate the line scan.

The main optical parameters to be specified are transmission $T_o$, focal length $F$, and $f$/number $F_\#$ or numerical aperture (NA). Since $\text{IFOV} = x/F$, the focal length determines the spatial resolution for a given detector. The NA is defined as the sine of the semi-cone angle of the output beam from the optics. It can be shown that if a diffuse (Lambertian) source emits $W$ W m$^{-2}$ into a hemisphere, the radiance due to the source in the focal plane is $WT_o(NA)^2$. $F_\#$ is defined as the ratio of focal length to diameter, and for a distant object $NA = 1/(2F_\#)$, so the ratio of the irradiance in the focal plane to the source radiance is:

$$\frac{\text{Irradiance in focal plane}}{\text{Radiance from extended object}} = \frac{T_o(\lambda)T_s(\lambda)}{4F_\#^2}$$

(35.11)

Transmission of thermal imaging optics is typically 60% to 90%, depending on complexity. The transmission of any optics between the temperature reference and the target must be known for quantitative measurement.

The imaging performance of a lens can be indicated by the size of the spot generated in the focal plane by a distant point object, and accurate results can be obtained if the intensity as a function of the angle $\alpha$ from the center of the image (point spread function, PSF) is known. A more usual approach is to use
the modulation transfer function (MTF), defined as the ratio of the contrast of the image of a target with a sinusoidal spatial variation in intensity to the contrast of the target itself. The MTF depends on the spatial frequency \( f \) of the target (expressed in cycles per radian) and on the wavelength of the radiation. For perfect optics of diameter \( D \), diffraction gives the following values for PSF and MTF, which are also plotted in Figure 35.10:

\[
\text{PSF}(a) = 4 \left[ \left( \frac{\lambda}{\pi D a} \right) J_1 \left( \frac{\pi D a}{\lambda} \right) \right]^2
\]

(35.12)

where \( J_1 \) is the Bessel function.

\[
\text{MTF}_o(f) = \frac{2}{\pi} \left\{ a \cos \left( \frac{\lambda f}{D} \right) - \frac{\lambda f}{D} \sqrt{1 - \left( \frac{\lambda f}{D} \right)^2} \right\}^2
\]

(35.13)

In practice, optics are frequently far from the diffraction limit, so manufacturers' figures must be used. If a thermal imager is to be used for measurement, correction for MTF will be required unless the IFOV and the PSF are both smaller than the region over which the temperature is to be measured. The signal level for a subresolution point source can be obtained by integrating the PSF over the detector area. For diffraction-limited optics, a rule of thumb for the LWIR band is that the diffraction spot diameter in mrad is the reciprocal of the lens diameter in inches (or \( 25/D \) when \( D \) is in millimeters).
35.8 Temperature References

If a thermal imager is to be used for measurement, it is generally necessary to compare the signal from the target with that from one or more bodies at known temperature. The most precise results are obtained if two bodies at different known temperatures and having the same emissivity as the target (e.g., painted with the same paint type) are placed adjacent to the target and the target temperature is deduced by interpolation. There is then no dependence on emissivity, atmospheric transmission, and optical transmission. Outside the laboratory this is seldom practical, however, and it is necessary to use thermal references within the imager itself. The fewer optical components there are between the reference and the scene, the better will be the accuracy. If the interior of a cavity of uniform temperature is viewed through a small hole, the emission from the hole follows the Planck equation accurately, irrespective of the emissivity of the interior surface of the cavity. Although very accurate, such a blackbody cavity is usually inconveniently large, and it is more usual to use a blackened surface with deep grooves or pits to give high emissivity.

Unless the detector has only one element, thermal references are also desirable if not essential to allow the outputs of the different detector elements to be equalized.

35.9 Imager Performance

SNR and NETD

If the target is larger than the IFOV and the PSF, the signal level due to a small temperature difference is found by multiplying the source differential output, the atmospheric and optical transmissions, the geometric attenuation due to the f-number, the detector area, and the responsivity as derived or defined in the previous sections, and integrating over the imager passband to give:

![Point Spread Function and MTF](image)
The noise voltage \( V_n \) is given by Equation 35.7, so the signal-to-noise ratio is obtained. If the number of serial detector elements is \( N_s \), the signal level is increased by this factor; but since the noise is uncorrelated between the elements, it increases only as \( \sqrt{N_s} \), so SNR improves as \( \sqrt{N_s} \). The SNR also improves as the square root of the number of parallel channels, since the dwell time is increased, giving a reduction in bandwidth \( B \).

The sensitivity of a thermal imager for large targets is normally defined in terms of its noise equivalent temperature difference (NETD) — the temperature difference between a large blackbody at zero range and its background — which gives a signal equal to the rms noise. This is given by \( V_n/V \) when \( \Delta T = 1 \), \( T_a = 1 \) and \( \varepsilon(\lambda) = 1 \), and is found to be:

\[
NETD = \frac{4F^2}{\int_0^\infty D^\lambda(\lambda)T^\lambda(\lambda)\varepsilon(\lambda)\frac{dW(\lambda,T)}{dT}d\lambda} \sqrt{\frac{B}{A_0 N_s}}
\]  

(35.15)

A good indication of signal-to-noise ratio is given if it is assumed that \( T_a \) and \( \varepsilon \) are constant within the imager passband, in which case SNR = \( \varepsilon T_a \Delta T/\text{NETD} \).

**Minimum Resolvable Temperature Difference**

The performance of a thermal imager is frequently defined by its minimum resolvable temperature difference (MRTD). MRTD(\( f \)) is the temperature difference between a four-bar square test pattern of frequency \( f \) c mrad\(^{-1} \) and its background required for an observer to count the imaged bars. The test is subjective, but has the advantage of characterizing the complete system and display, including any effects of nonuniformity. MRTD is proportional to NETD, and inversely proportional to the MTF and the square root of the number of frames presented within the integration time of the eye \( \tau_e \). The constant of proportionality depends on the degree of overlap between the scan lines. Discussion of the full MRTD model is beyond the scope of this chapter, but a simple expression (based on [1] p.167) — which gives an indication of performance for an imager with square detector elements without overlap and at least two samples per IFOV, and in which the electronics bandwidth is the same as that used for NETD calculation — is:

\[
\text{MRTD}(f) = \frac{3 \cdot \text{NETD} \cdot f \cdot \text{IFOV}}{\text{MTF}_e \text{MTF}_d \sqrt{\tau_e f_i}}
\]  

(35.16)

Calculation of MRTD is best performed using standard models, the most widely adopted being FLIR 92 [9].

**35.10 Available Imagers**

Recent advances in detector technology are only now beginning to be incorporated in commercially available systems. The result is that product ranges are currently changing rapidly, and prices are very unstable. The prices for uncooled systems in particular are likely to drop significantly in the near future as the market size increases. An indication of cost at present is:

- Military high-performance imagers $100,000–300,000
- Medium-performance imagers for measurement $30,000–100,000
- Uncooled imagers $10,000–30,000 (but falling rapidly)
Prices reflect not only performance, but ruggedness, environmental survivability, and image processing software. Military imagers in many countries are based on “common modules” that are sometimes multisourced, and that must be configured for specific applications. Table 35.1 lists some typical commercial imagers, which were selected to emphasize the wide variety of imager types, and the list must not be taken as a comprehensive survey. Some compact imagers weigh less than 2 kg, while some of the bench systems weigh over 100 kg. Accuracy of temperature measurement is not generally specified, but ±2 K or ±2% is a good figure for a calibrated imager. The information is based on published brochures, and there is every likelihood that improved models will be available by the time this book is published. It is strongly recommended that prospective purchasers should contact as many manufacturers as possible to obtain specifications and prices.

### 35.11 Performance Trade-offs

The expression for NETD presented earlier is appropriate for evaluation of existing systems where $D^*$ is known. To predict performance of future systems based on photon detectors, and to carry out design trade-offs, it is important to appreciate that $D^*$ is very dependent on conditions of use and on waveband. One reason is that the photons from an object of given temperature, although having a well-defined average flux, are emitted at random times. Statistical theory shows that if on average $N$ photons are collected within a given time interval, the standard deviation is $\sqrt{N}$ if $N$ is large enough to make the distribution Gaussian (as is almost always the case in the infrared due to the high background flux). This “photon noise” frequently predominates, in which case the detector is referred to as BLIP (background-limited photodetector). The $D^*$ is then determined more by the conditions of use than by the detector itself. If the efficiency of the cold shield $\eta_c$ is defined as the ratio of the effective $f$ number for the background flux to that of the signal, the number of background electrons generated within an integration time $\tau$ is given by:

</table>
For the reasons discussed above, the rms electron noise for a BLIP device within time \( \tau \) is simply the square root of the above figure. If the detector also has read-out noise of \( N_e \) electrons rms, this could be regarded as the noise that would be caused by a background flux that caused the generation of \( N_e^2 \) photoelectrons, so the noise can be written as:

\[
\text{Noise} = \sqrt{N_e + N_n^2} \text{ electrons rms} \tag{35.18}
\]

The signal due to a temperature difference of 1 K between target and background expressed in electrons within the integration time is:

\[
\text{Signal} = \frac{\tau A_b}{4F^2} \int_0^\infty T(T)T(\lambda)\eta(\lambda) \frac{dN(\lambda,T)}{dT} \, d\lambda \tag{35.19}
\]

Thus, the signal-to-noise ratio for \( \Delta T = 1 \) K is found, NETD being simply \( 1/\text{SNR} \) when \( T_e = 1 \).

For staring systems, and some scanning systems, the integration time is limited by saturation. If the maximum number of electrons that can be stored is \( N_m \), we find that the maximum integration time is:

\[
\tau_m = \frac{4F^2 \eta^2 N_m}{A_b \int_0^\infty N(\lambda)\eta(\lambda) \, d\lambda} \tag{35.20}
\]

When the integration time is controlled to restrict the number of electrons generated within the sampling interval to \( \tau_m \), the noise is given by letting \( N_e = N_m \) in Equation 35.18, so is independent of \( f/\text{number} \). If one also substitutes \( \tau_m \) for \( \tau \) in Equation 35.19, and divides Equation 35.19 by Equation 35.18, to obtain SNR, one obtains:

\[
\text{SNR} = \frac{\Delta T \eta^2 N_m \int T(T)T(\lambda)\eta(\lambda) \frac{dN(\lambda,T)}{dT} \, d\lambda}{\sqrt{N_m + N_n^2} \int N(\lambda)\eta(\lambda) \, d\lambda} \tag{35.21}
\]

The ratio of integrals is effectively the contrast of the scene behind the optics, which is further reduced by the inefficiency of the cold shield; thus, performance depends mainly on image contrast at the detector and the number of electrons stored. (Quantum efficiency essentially cancels out; and for a saturated device, \( \sqrt{N_m} \) is usually greater than \( N_n \).)

The above formulae are sufficiently general to allow trade-offs for photon detectors to be carried out against aperture, waveband, range, and frame rate, the main uncertainty being the read-out noise. For staring array detectors with processing on the focal plane, a typical figure is \( N_e = 1000 \), but much better (and worse) values are possible. The SNR and NETD values obtained in this way are for a single pixel. If the samples overlap spatially, the SNR is improved by the square root of the overlap factor. In practice, nonuniformity of the detector array will introduce spatial noise that will affect MRTD; and even after
electronic correction, this is frequently the main limitation on performance. Nonuniformity effects are discussed in [10] and [11].

The resulting trade-offs are discussed at some length in [12]. It is observed that if the integration time is controlled to prevent saturation, NETD is independent of $f$/number and quantum efficiency, but depends strongly on image contrast. This tends to favor the MWIR band, and makes high cold-shield efficiency crucial. The problem can be overcome in the LWIR by operating at a high frame rate, which has no effect on NETD but improves MRTD due to eye integration. For long-range applications, it is frequently necessary to use long focal lengths, giving large $f$/numbers if the optics diameter is to be kept within reasonable bounds. Under these conditions, saturation is less likely, and the high photon flux in the LWIR is necessary to overwhelm the read-out noise. If high spatial resolution rather than sensitivity is required, the MWIR band has a much better diffraction limit. Figure 35.11 indicates the ways in which the various limitations combine to define the combination of IFOV and waveband that gives optimum performance when it is necessary to resolve a given spatial frequency; the positions of the lines on this chart are of course peculiar to the system under investigation.

**35.12 Future Trends in Thermal Imaging**

At the high-performance end of the market, the developments are most likely to be driven initially by military requirements. Many countries already have thermal imaging common module programs, and many developments will be aimed at productionizing these modules to reduce cost and enhance performance. Multispectral instruments to aid in camouflage penetration and to broaden the conditions of operability through the atmosphere can be taken out of the laboratory into service. Currently, these are mainly scanning devices using adjacent long linear arrays of LWIR and MWIR detectors. For spectral agility, detector arrays based on multi quantum-well (MQW) technology can be used, since they can be tuned to some extent by varying the electrical bias. Multispectral refracting optics are complex and have poor transmission, so reflecting optics are generally used. Multispectral systems will allow more accurate compensation for emissivity, but their high cost might limit their use except for high-value applications such as earth resources surveys in aircraft or satellites. Techniques employed include frame-sequential filtering and imaging Fourier transform spectroscopy.
For commercial thermal imaging, the main thrust is likely to be cost reduction via the use of uncooled imagers, and in packaging to provide increased ease of use and functionality using in-built software. Optics cost can be reduced or performance improved by the use of hybrid aspheric components, which are now practical due to improvements in diamond turning. A diffractive surface is generated on one surface of a refracting lens. Because the power of a diffractive component is proportional to wavelength, a very low diffractive power can compensate for the chromatic aberration of the lens. This allows the use of materials such as zinc sulfide, which would otherwise be unacceptable due to chromatic aberration, but which have other desirable properties such as low cost or a low thermal coefficient of refractive index.

36.1 Heat and Other Thermal Signals
Calorimetry is the science of measuring heat or thermal signals. This chapter begins by explaining thermal and other signals. For a correct understanding of calorimetry, knowledge of thermodynamics is necessary; however, space permits an introduction only. An overview of the most important types of calorimeters, followed by some of the many applications, will then be presented. For those who want to do measurements without having to make their own devices, an overview of the most important calorimeters, and their vendors and approximate prices will be given. The chapter concludes with some
hints on present and future developments, and on further reading, since there is a large amount of literature on calorimeters.

**Signal Domains**

In measurement science, physical quantities can be distinguished by six different so-called signal domains [1]. All signals in calorimeters are either thermal signals or other signals that are transduced into thermal signals. The thermal signal (heat, for example) is then transduced into an electrical signal. In addition to the domains of thermal and electric signals, there is also the domains of the chemical, the mechanical, the magnetic, and the radiant signals. Calorimetric measurement of signals occurs from all domains [2]. Many of them are described in different sections of this Handbook. Calorimeters usually measure the thermal effects of (bio)chemical or mechanical processes, or they measure the thermal effect of temperature changes on matter.

**Heat and Temperature**

One of the forms in which energy can be present in a system is the random, internal kinetic energy of the particles (molecules or atoms) of a system, which can intuitively be called “thermal energy.” This is to be distinguished from the average, external movement of a system of particles as a whole, which can be called the “mechanical energy” of the system. For gases, thermal energy is closely related to the random velocity of the molecules; and in the case of multi-atom molecules, the rotations and vibrations of the atoms within the molecules. The zeroeth law of thermodynamics states that, if two systems are each in equilibrium with a third system, they will be in equilibrium with each other. They are said to have the same temperature. For gases, statistical mechanics shows the direct relation between the thermal energy (or heat) stored in the system and temperature [3]. This law, however, also applies to liquids and solids, although the quantitative relation between thermal energy (agitation of the particles) and temperature is less straightforward and not so easy to calculate as for gases. Temperature and thermal energy distribution can be viewed as the result of statistical processes, such as diffusion. Diffusion ensures that if ever there is a surplus of thermal energy (i.e., of fast molecules or electrons, or a higher density of phonons) in some area, some of it will flow toward areas with a lower thermal energy density until thermal equilibrium has been established. This flow of energy $P$ (in $W = J s^{-1}$) is called heat flow. Heat flow is therefore the transfer of (thermal) energy from one (part of a) system to another. Note that heat is not conserved, because a change in thermal energy of a system may be achieved by heat exchange with the environment, but also by mechanical interaction, and heat can be used to do mechanical work (motor!) just as well as heating up a system. Heat can be viewed as “thermal energy on the move,” but whether it ends up as thermal, mechanical or another form of energy depends on the circumstances.

**Work and Enthalpy**

The first law of thermodynamics is also of importance for calorimetry. In a simple form, in the absence of other forms of energy exchange, it states that the change in internal energy $\Delta U$ of a system is equal to the heat $Q$ supplied by the ambient to the system, minus the work (mechanical energy) $p\Delta V$ done by the system on the ambient:

$$\Delta U = Q - p\Delta V$$

(36.1)

This is of importance when measuring the specific heat capacity $c$ (in $J kg^{-1} K^{-1}$) of matter. This measurement can be performed under two conditions: at constant volume $V$ and at constant pressure $p$. At constant volume, no work will be done by the system, since $p\Delta V = 0$. So, the specific heat capacity at constant volume $c_v$ is simply the change in internal energy. The specific heat capacity of a system at constant pressure $c_p$ is (usually) higher, since additional energy (heat) is needed to perform work on the ambient: $p\Delta V$. The quantity combining these contributions to the energy at constant pressure is called
enthalpy \( H \), and the change in enthalpy vs. temperature (in J K\(^{-1}\)) at constant pressure is the specific heat capacity \( C_p \) of a sample at constant pressure:

\[
C_p = \frac{dH}{dT}\bigg|_p.
\]

### 36.2 Calorimeters Differ in How They Relate to Their Surroundings

In essence, a calorimeter performs three functions: it encloses a chamber in which a thermal experiment is carried out; it measures the heat exchange between the sample under test and the calorimeter (and often other quantities are being measured as well, such as temperature and amount of substance); and it thermally separates the experimental chamber from its surroundings. There exist many types of calorimeters. They all have an experimental chamber. Apart from this, four essential criteria can be used to classify calorimeters [4, 5]. The first criterion is, what does the calorimeter do with the heat that is generated (or absorbed) by the experiment? The second criterion is, how does the calorimeter relate to its surroundings? The third criterion is, does it measure a single experimental sample, or is it a twin design with a reference compensating for common mode errors? The fourth criterion is, does the calorimeter function at a fixed temperature, or can it scan a temperature range? Table 36.1 lists the various possibilities for the relation to the surroundings, and for the heat measurement. In principle, almost every combination is possible. In practice, some combinations naturally go together because they compensate for their strengths and weaknesses. For example, calorimeters in which the experimental temperature is scanned often use a twin configuration to eliminate the common mode errors arising from the continually changing temperature.

### Isothermal Calorimeters

In the isothermal calorimeter, the experiment is always kept at a fixed temperature. This is attained by instantly removing (or supplying) any heat that the experiment releases (or absorbs). The isothermal calorimeter was the first to be developed. In 1780, Lavoisier and Laplace made the “ice calorimeter” in which the heat generated by the experiment is used to melt ice into water. If enough ice is available, the calorimeter will remain at 0°C, regardless of the progress of the experiment. The experimentally generated heat \( Q \) (J) is calculated by weighing the mass \( m \) (kg) of the melt water and multiplying by the heat of the ice-water transition \( q_{\text{fus}} \) (J kg\(^{-1}\)):

\[
Q = m \, q_{\text{fus}}
\]

(36.2)

The experiment with the melting ice is enveloped within a thermostat, which consists of a double-walled vessel with melting ice between the walls, which is always at 0°C as well. Thus, the isothermal calorimeter has a perfect thermal isolation between experiment and surroundings in the form of a second guard-vessel that buffers all the heat coming from the surroundings.

### Phase-Transition or Thermoelectric Compensation of the Heat

In the isothermal calorimeter, the heat generated by the experiment is immediately absorbed by the calorimeter. This can be accomplished by phase-transition compensation of the heat, e.g., by melting of
solids or evaporation of liquids. But nowadays, compensation by electrical means is preferred because it can be measured so easily. Thus, heat $Q$ (J) absorbed by the experiment is replaced using Joule heating (dissipation of heat by a current $I$ (A) through an electric heater with resistance $R_h$ (Ω)), while heat generated by the experiment is absorbed by Peltier coolers:

$$Q = \int I^2 R_h \, dt$$  \hspace{1cm} (36.3)

36.3 Adiabatic Calorimeters Often Measure Time-Dependent Temperature Differences

In the adiabatic calorimeter, no heat exchange with the surroundings is allowed, and all the heat generated by the experiment is used to increase the temperature of the calorimeter. The amount of heat $Q$ (J) generated follows from the temperature increase $\Delta T$ (K), divided by the heat capacity of the calorimeter $C_c$ (K J$^{-1}$):

$$Q = \Delta T / C_c$$  \hspace{1cm} (36.4)

The absence of heat exchange with the surroundings of the calorimeter is obtained by immersing the experimental chamber of the adiabatic calorimeter in an outer vessel; see Figure 36.1. The temperature of the outer vessel is kept at the same (increasing) temperature as the experimental chamber by means of electronic feedback, heating the outer vessel to maintain a practically zero temperature difference. In the adiabatic calorimeter, one must wait a few minutes after the experiment has finished to allow the heat to spread itself uniformly over the chamber and to obtain the final temperature. In Figure 36.1, the experimental chamber is a so-called “calorimetric bomb” in which fuel is fully burned to measure its heat of reaction. The bomb is immersed in a vessel filled with water — the inner vessel. A stirrer assures fast heat exchange between the bomb and the inner vessel, thermometers measure the temperature of the inner vessel and the outer guard vessel. The outer vessel is regulated to the inner-vessel temperature by means of electrical heaters and refrigerator coolers.

Isoperibol and Heat Flux Calorimeters

The term isoperibol was devised to indicate a calorimeter having “uniform surroundings.” In this calorimeter, the outer shell provides a reference temperature, and customarily, the experiment starts at the same temperature. The experimental chamber is connected to the outer shell by a well-defined thermal conductance. Any heat generated by the experiment will cause a well-defined temperature difference $\Delta T$ (K) across the thermal conductance $G_{th}$ (W K$^{-1}$), and this temperature difference is subsequently measured as a “local temperature difference.” Calorimeters utilizing this way of measuring the heat are referred to as “heat flux calorimeters;” and often measure the power $P$ (J s$^{-1}$ or W) generated by the experiment, rather than the energy:

$$P = \Delta T \, G_{th}$$  \hspace{1cm} (36.5)

Scanning Calorimetry Sweeps the Experiment Temperature

While calorimeters are over 200 years old, a recent innovation is that of the scanning calorimeter. In the scanning calorimeter, the experimental chamber is not kept at (approximately) one temperature, but it is swept over a temperature range. The temperature is increased at a given rate (e.g., 10 K min$^{-1}$) by electric heating, or decreased by, for example, cooling with liquid nitrogen. To achieve the temperature sweep, the experiment is placed inside a computer-controlled oven. To compensate for common-mode errors
(i.e., back-logging or deviation of the sample temperature from the oven temperature, and imperfections in the oven temperature profile with respect to time and location), scanning calorimeters are often built with twin experimental sites for which the difference is measured. One site is for the sample under test; the other site serves as reference, which is either left empty or contains material resembling the sample under test as much as possible, except for the phenomena to be measured. Such calorimeters are called differential scanning calorimeters, DSCs (see “Further Information” for a general book on DSC). Three different types of DSCs are common. The first type is the DSC based on heat flux measurement; see Figure 36.2. In this, the reference and the sample are both heated by the oven through a thermal resistance (gaseous or a solid circular disk). In Figure 36.2, the heating block is the oven, while the (constantan) disk is the path from oven to sample and reference, assuring both heat conduction from oven to sample/reference. The disk also forms a well-defined heat resistance from sample to oven, to measure the heat generation and absorption in the sample using thermocouples that measure the resulting temperature differences. Because of the small size of the experimental site and sample (typically less than 1 cm diameter and 0.1 mL volume), the DSC is usually very fast, and the temperature curve is an accurate representation of the momentaneous heat production in the sample. In the second type of DSC — the power compensation DSC — the temperature of the sample and the reference are both measured with platinum resistors. Sample and reference each have an individual heating source, which is electronically
controlled to maintain sample and reference on the required temperature course. The difference between reference and sample heating power immediately gives the experimental heat. In the third (less accurate) type, only the temperature at which phenomena occur is registered. This type can be used for bigger samples (2 to 3 mL against 0.1 mL for the heat-flux DSC), or at very high temperatures up to 2000°C.

Converting the Measured Curve to the Actual Progress of the Experiment

Due to the thermal resistance and the heat capacitance inside the experimental chamber of a calorimeter, there is a time constant associated with distributing the experimental heat over the chamber, and reaching the final temperature. A heat pulse does not create a temperature pulse, but rather a smeared-out curve. In a DSC, this smearing-out is usually not significant because of the small time constant (1 to 3 s). For some other instruments, so-called curve desmearing has to be carried out using convolution integrals to extract all the information from the measurement curve. With commercially available instruments, software is often supplied that does the job for you, but the accuracy of this software is not satisfactory in all cases, so one might need to do some further study on desmearing [4].

Calibration of Calorimeters

The inaccuracy of the calorimeter can be reduced by calibration. Heat production can easily be simulated electrically. Unfortunately, the thermal leakage of the electric leads reduces the accuracy of this method. More common, therefore, is the use of reference materials with a known heat of transition or reaction for calibration. For bomb calorimeters, the response can be calibrated using the heat of reaction of benzoic acid, which has been carefully determined to be 26,457 J g⁻¹ [6]. For a DSC, a range of materials can be used for calibration. This is due to the wide range of applications, and also to the wide range of

FIGURE 36.2 The heat flux differential scanning calorimeter (DSC) consists of two experimental sites on a heat-conducting disk. Heat generation in the sample pan results in a temperature increase of the sample with respect to the reference, measured by thermocouple (the disk being one part of the couple).
temperatures used. Generally, one or more metals are used for calibration of both the power and the temperature scale; for example, indium, which has a melting point of 156.6°C, and an enthalpy of melting of 28.6 J g⁻¹. The uncertainty of the value for the heat of fusion (in this case, of melting) is about 0.5%. This is the limit when calibrating in this manner. Basically, DSC inaccuracy is around a few percent. For up-to-date details on calibration and the calibration materials, please consult [7, 8], the references given there, and the most recent data published, since calibration procedures for the DSC are still improving. Specific heat capacity measurements are often performed in three steps. First, the baseline-offset of the DSC is measured with empty reference and empty sample sites (one measures the difference between sample and reference baseline, i.e., the systematic asymmetry of the instrument). Then, a measurement of a reference material with accurately determined specific heat capacity is made; for this, sapphire (crystalline Al₂O₃) is often used. Finally, a measurement of the unknown sample is carried out. By correcting for the baseline-offset, and division of the measurements of the known and the unknown samples, the specific heat capacity of the unknown sample can be determined. Currently, these corrections are all made by the computer controlling the DSC [9].

36.4 Typical Applications of Calorimeters

Specific Heat, Transition Heat and Temperatures

Specific heat capacity can be measured by accurate point-wise measurements, but measurement with a DSC is much more efficient. With the DSC, one also obtains the temperature and heat of phase transitions by enthalpy measurement at the transition temperature. Many materials also exhibit changes in crystallization at some given temperature (e.g., glass transition points). Also, these are transition points with their specific heat and temperature, and these can be measured with DSC as well.

Analysis of Chemical and Physical Reactions

Calorimetry is very well suited for analysis of chemical reactions. In particular, the heat of exothermic and endothermic reactions can be determined. An important example is the calorific value of fuels. Households and factories buying fuels are primarily interested in the calorimetric value of their purchases. The so-called oxygen bomb calorimeter is indispensable for primary calibration in this application. The oxygen bomb is usually an adiabatic calorimeter, in which a sample of the fuel (such as solid coal, liquid oil, or gaseous methane) is brought together with an excessive amount of oxygen (e.g., at a pressure of 30 bar). Then, the mixture is ignited, and the heat of burning will spread over the bomb, until equilibrium is reached. The temperature increase of the bomb, divided by the heat capacity of the device, gives the heat of reaction. In general, corrections have to be made for volume and pressure changes (work!) as liquids or solids are burned and converted to gases and liquids, and also for the additional heat capacity and for the transition heat of the reaction products. Of course, chemical reactions other than burning of fuel can be analyzed in this way as well. In a slightly modified version, the adiabatic calorimeter can also serve to analyze, for example, weak bases and weak acids that do not easily respond to other analysis methods. Similarly, the heat of mixing two solutions, of dissolving a solid in a solvent, of diluting a mixture, and even the heat of wetting can be determined in this so-called solution calorimeter.

36.5 Thermal Analysis of Materials and Their Behavior with Temperature

Apart from directly measuring chemical reactions, one can also analyze materials by exposing them to a temperature sweep, either in an inert atmosphere (nitrogen or helium) or in an oxidizing atmosphere.
Then, all effects — such as glass transition, crystallization, melting, evaporation, decomposition, and even oxidation — can be detected. For this, a DSC is again utilized. In the more expensive analysis systems, DSC instruments often offer the possibility of incorporating other techniques. Mass changes due to oxidation and evaporation are detected by thermogravimetry (TG). This is accomplished by placing the entire experimental chamber on a balance, that continuously measures the sample mass. These data are available as a function of temperature as well, parallel to the heat data. The DSC inner gas atmosphere is usually refreshed continuously using purge gas. This makes it possible to collect the gases coming from the calorimeter furnace and subject them to further analysis, such as mass spectrometry (MS), gas chromatography (GC), Fourier transform infrared analysis (FTIR), and other analysis methods. With sensitive DSC, it is thus possible to detect almost any structural change in matter as a function of temperature. Figure 36.3 shows a drawing of a combined DSC and TG instrument, capable of analyses up to 2000°C. The DSC-TG sample carrier is accurate up to 1500°C, using heat transfer from oven to samples carrier by the surrounding purge gas. Radiation shields are required to reduce heat losses by infrared radiation, which is significant at high temperatures.

**Biological Analysis from Cells to Entire Human Beings**

Calorimetry is not just the measurement of thermal effects in 1-mL samples. Calorimeters receiving entire human beings are available as well. In practice, there is a wide range of application of calorimeters to biology. This is not surprising, since all forms of live produce heat in activity and often also in rest. The first calorimeters were already used to measure the heat produced by animals. But also, the study of cells (with their heat production of about 1 pW [10]) and the efficiency of enzymatic conversions can be studied using calorimetry. Microcalorimetry is used for very small effects, sometimes using microtechnology to fabricate very small and very sensitive calorimeters [11, 12]; see [10] for an overview and
many references. Some microcalorimeters are already being commercialized, using integrated-circuits technology to make very sensitive sensors. Figure 36.4 shows such microcalorimeters encapsulated in a ceramic housing. So far, the use of these sensors is restricted to isoperibol operation around room temperature [11], using aluminum heat sinks to provide the reference temperature. Applications of calorimetry are also found in the food industry, for routine analyses, ecology, plants, etc. See [13, 14] for collections of papers on these subjects.

Summary

The applications of thermal analysis are overwhelming in number. In many cases, when wanting to learn more about materials, thermal analysis can add insight. Some applications were mentioned above. In Table 36.2 some of the often-encountered applications for various disciplines are listed.

36.6 Choosing the Proper Calorimeter for an Application

When faced with a practical analysis problem, one can choose between many instruments. The three main categories are the DSC, the calorimetric bomb or solution calorimeter, and the large reaction or fermentation calorimeter.

What Do You Want To Measure?

If one wants to measure specific heats of reaction, of oxidation, solution, etc., at room temperature, a calorimetric bomb or a solution calorimeter might be the first choice. They are accurate and economical. If one wants to optimize a chemical or biological process, reaction calorimeters or fermentation calorimeters might be the choice. In almost all other cases, a DSC will be the most effective instrument. A

FIGURE 36.4 In microcalorimetry for (bio)chemical analyses, flow-through systems allow continuous, on-line measurement of (bio)chemical quantities in microliter reaction chambers, using $5 \times 5$-mm silicon microchips coated with enzymes or living cells.
DSC is especially useful when one wants to obtain the thermal behavior of materials as a function of temperature. In turn, the temperature-dependent behavior of materials can tell a lot about their structure, their properties, and even their thermomechanical history. Important is the scanning range and rate of the DSC. In some cases, the measurement problem cannot be solved by a standard available calorimeter, and one is forced to either use an experimental calorimeter or develop a special-purpose calorimeter.

**Budget, and the Need of Pre- and After-Sales Service**

A cost-effective DSC will cost about $25,000, the most expensive models can cost up to $150,000 and include thermogravimetric measurement. Calorimetric bombs are somewhat cheaper, starting at $18,000. The large reaction calorimeters are more costly, at about $120,000 and above. Finally, one can buy experimental instruments or make one’s own system. An adiabatic system consisting of a Dewar in a polystyrene housing, using a commercially available stirrer and platinum resistance (measured with any 5½ digit DMM) will put you in business, although at reduced accuracy. However, the budget for this will not need to exceed much more than about $1000 (excluding the DMM). It is less advisable to make one’s own DSC (for cost reasons) or calorimetric bomb (for cost and safety reasons).
36.7 Can the Instrument of Choice Measure the Signals Desired?

Here, various parameters must be considered. Accuracy, the degree to which an instrument reading approaches the true value, lies around a few percent for DSCs and parts-of-percent for adiabatic calorimeters. Repeatability of the major calorimeter measurement results — such as heat peak area and peak starting temperature — depends, among other things, on such matters as baseline noise/drift, influence of sample preparation, and positioning in the DSC sample site. Resolution should be considered for two parameters: heat and temperature. First, there is the sensitivity of the instrument for generated heat or power, related to its noise. For DSCs, resolution for power is usually around 0.1 μW to 10 μW; for bomb calorimeters, resolution for heat is around 0.1 J to 10 J. But there is also the resolution of a DSC for separating two heat pulses at two nearby temperatures. This can be designated as the temperature resolution, and depends on time constant and heating rate. Finally, there is the point of linearity and time constant. In case the time constant of the instrument is much larger than that of the process, good linearity is required if one wants to “desmear” the measured curve and obtain the actually produced heat as a function of time. But, a current DSC is a very fast instrument, and desmearing is not really necessary anymore. So, linearity is less important for fast DSCs.

Instrument Control and Data Management

Software is becoming more and more important. Since it will control the measurement, its user-friendliness determines how easy and how error-free one can operate the instrument. It also can take care of analysis of the measurement results, and graphical and numerical presentation of the results. The software can also take care of quality-control aspects of analysis, such as writing to file all the measurement details (not only what was measured, but also how it was measured). Presently, top models of all three types described above will perform these functions. With DSC instruments, software can often be used to control all kinds of thermal analysis instruments apart from the DSC, such as TG, DMA, etc., and merge results obtained with DSCs, TG, DMA, and other analysis techniques. This facilitates interpretation of measurements.

36.8 Commercially Available Calorimeters

Tables 36.3 and 36.4 describe the different instruments and vendors. Table 36.3 gives an overview of instruments and some characteristics, while Table 36.4 gives vendor information. Tables 36.3 and 36.4 are (necessarily) incomplete since only the major vendors have been listed; thus, if looking for a calorimeter, please complete the list with local (and up-to-date) information.

36.9 Advanced Topic: Modulated or Dynamic DSC Operation

Modulating the Temperature Scan Improves Insight into the Measurement

One of the recent developments in DSC is the use of a nonuniform temperature scan. On the standard temperature increase (for example, 1 K min⁻¹), an alternating fast temperature change is superimposed, which can be a sinusoidal signal. Alternatively, a stepped temperature profile can be used. Here, the temperature is increased during, for example, 0.5 min with 2°C, and then stabilized for 0.5 min, resulting in an overall scan rate of 2°C min⁻¹. In fact, the scan is now modulated with a block wave of amplitude 2°C min⁻¹, see Figure 36.5(a). For an instrument with small time constant, such as the DSC-7 of Perkin
Elmer at about 1 to 2 s, this means that the heat flow for increasing the experiment temperature in the stabilization time will be completely stopped. Any heat flows remaining result from processes in the sample itself; see Figure 36.5(a). Proper interpretation of the measurement results obtained by this method is still under discussion by Reading [15], Schawe [16], and many others.

**PET Is Often Used as Example**

Figure 36.5(b) gives the analysis of PET (polyethylene terephthalate), a polymer often used as a reference material because of its convenient and exemplary behavior in polymer analysis [17]. The curve is that of shock-cooled PET, i.e., the PET (from an ordinary beverage bottle) is heated to 300°C in a nitrogen atmosphere, and then quench-cooled in 1 min to maintain an amorphous structure. Six regions can be seen. From 50°C to about 75°C, the heat capacity of the PET sample requires power to achieve the temperature increase. At about 75°C, the so-called “glass transition” takes place, where reordering of the PET molecules takes place, increasing the specific heat of PET (an endothermic process), as can be seen from the lifting of the baseline (even at zero temperature increase, heat has to be supplied to the PET). Then follows a region with increased specific heat, caused by the higher freedom of movement of the

PET molecules compared to the structure below glass transition. Around 140°C, cold crystallization of the material occurs: again a reordering of the material. This is a strongly exothermic process, which again displaces the baseline. The power to be supplied to the sample then steadily increases, and also, with rising temperature, the baseline starts to fall again until a maximum just below melting at 250°C. This is the result of further crystallization, which is facilitated by the higher energy in the sample, and the much better mobility of the molecules just before melting. In the modulated DSC, recrystallization and melting are two concurring phenomena that can be distinguished. Similarly, the hope is that glass transition and cold crystallization can be better distinguished in materials where they overlap (in PET, they are clearly distinct).

Acknowledgments

The author wishes to thank Dr. P. J. van Ekeren of Utrecht University and Dr. G. W. H. Höhne of Universität Ulm for their suggestions in improving this chapter.
FIGURE 36.5  In modulated or dynamic DSCs, the temperature is not increased at a given rate, but modulated with a sinusoidal or stepwise deviation (a) to separate heat transfer due to temperature increase (specific heat), and heat transfer due to phase-changes in the material (glass transition, crystallization, melting). The heat flow in dynamic a DSC for shock-cooled PET (b) clearly shows the absence of heat flow in regions without material change (only temperature increase), and also the residual heat flow when not increasing temperature due to glass transition (≈75°C), cold crystallization (≈140°C), and melting (≈250°C). 37.1 **Meter Voltage Measurement**

Instruments for the measurement of electric voltage are called *voltmeters*. Correct insertion of a voltmeter requires the connection of its terminals to the points of an electric circuit across which the voltage has to be measured, as shown in Figure 37.1. To a first approximation, the electric equivalent circuit of a voltmeter can be represented by a resistive impedance $Z_v$ (or a pure resistance $R_v$ for dc voltmeters). This means that any voltmeter, once connected to an electric circuit, draws a current $I_v$ given by:

$$I_v = \frac{U}{Z_v}$$  \hspace{1cm} (37.1)

where $U$ is the measured voltage. The higher the value of the internal impedance, the higher the quality of the voltmeter, since it does not significantly modify the status of the electric circuit under test.

Different operating principles are used to measure an electric voltage. The mechanical interaction between currents, between a current and a magnetic field, or between electrified conductors was widely adopted in the past to generate a mechanical torque proportional to the voltage or the squared voltage to be measured. This torque, balanced by a restraining torque, usually generated by a spring, causes the instrument pointer, which can be a mechanical or a virtual optical pointer, to be displaced by an angle proportional to the driving torque, and hence to the voltage or the squared voltage to be measured. The value of the input voltage is therefore given by the reading of the pointer displacement on a graduated scale. The thermal effects of a current flowing in a conductor are also used for measuring electric voltages, although they have not been adopted as widely as the previous ones. More recently, the widespread diffusion of semiconductor devices led to the development of a completely different class of voltmeters: *electronic* voltmeters. They basically attain the required measurement by processing the input signal by means of electronic semiconductor devices. According to the method, analog or digital, the input signal is processed, the electronic voltmeters can be divided into *analog* electronic voltmeters and *digital*...
electronic voltmeters. Table 37.1 shows a rough classification of the most commonly employed voltmeters, according to their operating principle and their typical application field.

This chapter section briefly describes the most commonly employed voltmeters, both electromechanical and electronic.

**Electromechanical Voltmeters**

Electromechanical voltmeters measure the applied voltage by transducing it into a mechanical torque. This can be accomplished in different ways, basically because of the interactions between currents (electrodynamic voltmeters), between a current and a magnetic field (electromagnetic voltmeters), between electrified conductors (electrostatic voltmeters, or electrometers), and between currents induced in a conducting vane (induction voltmeters). According to the different kinds of interactions, different families of instruments can be described, with different application fields. Moving-coil electromagnetic voltmeters are restricted to the measurement of dc voltages; moving-iron electromagnetic, electrodynamic, and electrostatic voltmeters can be used to measure both dc and ac voltages; while induction voltmeters are restricted to ac voltages.

The most commonly employed electromechanical voltmeters are the electromagnetic and electrodynamic ones. Electrostatic voltmeters have been widely employed in the past (and are still employed) for the measurement of high voltages, both dc and ac, up to a frequency on the order of several megahertz. Induction voltmeters have never been widely employed, and their present use is restricted to ac voltages.

Therefore, only the electromagnetic, electrodynamic, and electrostatic voltmeters will be described in the following.

Electromagnetic Voltmeters

Dc Moving-Coil Voltmeters.

The structure of a dc moving-coil meter is shown in Figure 37.2. A small rectangular pivoted coil is wrapped around an iron cylinder and placed between the poles of a permanent magnet. Because of the shape of the poles of the permanent magnet, the induction magnetic field $B$ in the air gap is radial and constant.

Suppose that a dc current $I$ is flowing in the coil, the coil has $N$ turns, and that the length of the sides that cut the magnetic flux (active sides) is $l$, the current interacts with the magnetic field $B$ and a force $F$ is exerted on the conductors of the active sides. The value of this force is given by:

$$ F = NBlI $$  \hspace{1cm} (37.2)

Its direction is given by the right-hand rule. Since the two forces applied to the two active sides of the coil are directed in opposite directions, a torque arises in the coil, given by:

$$ T_i = Fd = NBldI $$  \hspace{1cm} (37.3)

where $d$ is the coil width. Since $N, B, l, d$ are constant, Equation 37.3 leads to:

$$ T_i = k_i I $$  \hspace{1cm} (37.4)

showing that the mechanical torque exerted on the coil is directly proportional to the current flowing in the coil itself.
Because of $T_r$, the coil rotates around its axis. Two little control springs, with $k_r$ constant, provide a restraining torque $T_r$. The two torques balance when the coil is rotated by an angle $\delta$ so that:

$$k_i I = k_r \delta \quad (37.5)$$

which leads to:

$$\delta = \frac{k_r}{k_i} I \quad (37.6)$$

Equation 37.6 shows that the rotation angle of the coil is directly proportional to the dc current flowing in the coil. If a pointer with length $h$ is keyed on the coil axes, a displacement $\lambda = h\delta$ can be read on the instrument scale. Therefore, the pointer displacement is proportional to the current flowing in the coil, according to the following relationship:

$$\lambda = h \frac{k_r}{k_i} I \quad (37.7)$$

This instrument is hence intrinsically a current meter. A voltmeter can be obtained by connecting an additional resistor in series with the coil. If the coil resistance is $R_c$, and the resistance of the additional resistor is $R_a$, the current flowing in the coil when the voltage $U$ is applied is given by:

$$I = \frac{U}{R_c + R_a} \quad (37.8)$$

and therefore the pointer displacement is given by:

$$\lambda = h \delta = h \frac{k_r}{k_i} I = h \frac{k_r}{k_i \left( R_c + R_a \right)} U \quad (37.9)$$

and is proportional to the applied voltage. Because of this proportionality, moving-coil dc meters show a proportional-law scale, where the applied voltage causes a proportional angular deflection of the pointer.

Because of the operating principle expressed by Equation 37.3, these voltmeters can measure only dc voltages. Due to the inertia of the mechanical part, ac components typically do not cause any coil rotation, and hence these meters can be also employed to measure the dc component of a variable voltage. They have been widely employed in the past for the measurement of dc voltages up to some thousands volts with a relative measurement uncertainty as low as 0.1% of the full-scale value. At present, they are being replaced by electronic voltmeters that feature the same or better accuracy at a lower cost.

Dc Galvanometer.

*General characteristics.* A galvanometer is used to measure low currents and low voltages. Because of the high sensitivity that this kind of measurement requires, galvanometers are widely employed as null indicators in all dc balance measurement methods (like the bridge and potentiometer methods) \[1, 2\].

A dc galvanometer is, basically, a dc moving coil meter, and the relationship between the index displacement and the current flowing in the moving coil is given by Equation 37.7. The instrument constant:
is usually called the galvanometer current constant and is expressed in mm μA⁻¹. The galvanometer current sensitivity is defined as \(1/k_a\) and is expressed in μA mm⁻¹.

According to their particular application field, galvanometers must be chosen with particular care. If \(k_a\) is taken into account, note that once the full-scale current and the corresponding maximum pointer displacement are given, the value of the ratio \(hk_i/k_r\) is also known. However, the single values of \(h\), \(k_i\), and \(k_r\) can assume any value and are usually set in order to reduce the friction effects. In fact, if the restraining friction torque \(T_f\) is taken into account in the balance equation, Equation 37.5 becomes:

\[
k_i I = k_i \frac{\lambda}{h} \pm T_f
\]  

(37.11)

where the ± sign shows that the friction torque does not have its own sign, but always opposes the rotation.

The effects of \(T_f\) can be neglected if the driving torque \(hk_iI\) and the restraining torque \(k_i\lambda\) are sufficiently greater than \(T_f\). Moreover, since the galvanometer is employed as a null indicator, a high sensitivity is needed; hence, \(k_a\) must be as high as possible. According to Equations 37.10 and 37.11, this requires high values of \(hk_i\) and low values of \(k_i\). A high value of \(h\) means a long pointer; a high value of \(k_i\) means a high driving torque, while a low value of \(k_r\) means that the inertia of the whole moving system must be low.

The pointer length can be increased without increasing the moving system inertia by employing virtual optical pointers: a little, light concave mirror is fixed on the moving coil axis and is lit by an external lamp. The reflected light hits a translucent, graduated ruler, so that the mirror rotation can be observed (Figure 37.3). In this way, a virtual pointer is obtained, whose length equals the distance between the mirror and the graduated ruler.

![FIGURE 37.3 Virtual optical pointer structure in a dc galvanometer.](image)
The reduction of the moving system inertia is obtained by reducing the weight and dimension of the moving coil, and reducing the spring constant. This is usually done by suspending the moving coil with a thin fiber of conducting material (usually bronze). Thus, the friction torque is practically removed, and the restraining spring action is given by the fiber torsion.

According to Equations 37.3 and 37.4, the driving torque can be increased by increasing the coil flux linkage. Three parameters can be modified to attain this increase: the induction field \(B\), the coil section \(ld\), and the number of turns \(N\) of the coil winding.

The induction field \(B\) can be increased by employing high-quality permanent magnets, with high coercive force, and minimizing the air gap between the magnet’s poles. This minimization prevents the use of moving coils with a large section. Moreover, large coil sections lead to heavier coils with greater inertia, which opposes the previous requirement of reduced inertia. For this reason, the coil section is usually rectangular (although a square section maximizes the flux linkage) and with \(l > d\).

If the galvanometer is used to measure a low voltage \(U\), the voltage sensitivity, expressed in \(\mu\text{V} \text{mm}^{-1}\), is the inverse of:

\[
k_v = \frac{\lambda}{U}
\]

where \(k_v\) is called the galvanometer’s voltage constant and is expressed in \(\text{mm} \mu\text{V}^{-1}\).

**Mechanical characteristics.** Due to the low inertia and low friction, the galvanometer moving system behaves as an oscillating mechanical system. The oscillations around the balance position are damped by the electromagnetic forces that the oscillations of the coil in the magnetic field exert on the coil active sides. It can be proved [1] that the oscillation damping is a function of the coil circuit resistance: that is, the coil resistance \(r\) plus the equivalent resistance of the external circuit connected to the galvanometer. In particular, the damping effect is nil if the coil circuit is open, and maximum if the coil is short-circuited.

In practical situations, a resistor is connected in series with the moving coil, whose resistance is selected in such a way to realize a critical damping of the coil movement. When this situation is obtained, the galvanometer is said to be critically damped and reaches its balance position in the shortest time, without oscillations around this position.

**Actual trends.** Moving-coil dc galvanometers have been widely employed in the past when they represented the most important instrument for high-sensitivity measurements. In more recent years, due to the development of the electronic devices, and particularly high-gain, low-noise amplifiers, the moving-coil galvanometers are being replaced by electronic galvanometers, which feature the same, or even better, performance than the electromagnetic ones.

**Electrodynamic Voltmeters**

**Ac Moving-coil Voltmeters.**

The structure of an ac moving-coil meter is shown in Figure 37.4. It basically consists of a pivoted moving coil, two stationary field coils, control springs, a pointer, and a calibrated scale. The stationary coils are series connected and, when a current \(i_f\) is applied, a magnetic field \(B_f\) is generated along the axis of the stationary coils, as shown in Figure 37.5. A magnetic flux is therefore generated, whose instantaneous values are given by:

\[
\Phi_f(t) = k'm_fi_f(t)
\]

where \(m_f\) is the number of turns of the stationary coil and \(k'\) is a proportionality factor. When a current \(i_m\) is applied to the moving coil, a torque arises, whose instantaneous values are proportional to the product of \(\Phi_f\) and \(i_m\) instantaneous values:

\[
T_f(t) = k''\Phi_f(t)i_m(t) = ki_f(t)i_m(t)
\]

© 1999 by CRC Press LLC
The driving torque is therefore proportional to the instantaneous product of the currents flowing in the two coils. Due to this driving torque, the moving element is displaced by an angle ($\delta t$), until the spring restraining torque $T_s(t) = k_s \delta(t)$ balances the driving torque. The moving element rotation is thus given by:

$$\delta(t) = \frac{k}{k_s} i(t) j(t)$$  \hspace{1cm} (37.15)$$

and, if the pointer length is $h$, the following pointer displacement can be read on the scale:

$$\lambda(t) = h \frac{k}{k_s} i(t) j(t)$$  \hspace{1cm} (37.16)$$

The proportionality factor $k$ is generally not constant, since it depends on the mutual inductance between the two coils, and thus on their number of turns, shape and relative position. However, if the two coils are carefully designed and placed, the magnetic field can be assumed to be constant and radial in the rotation area of the moving coil. Under this condition, $k$ is virtually constant.

Because the bandwidth of the moving element is limited to a few hertz, due to its inertia, the balance position is proportional to the average value of the driving torque when the signal bandwidth exceeds
this limit. If $i_f$ and $i_m$ currents are sinusoidal, with $I_f$ and $I_m$ rms values, respectively, and with a relative phase displacement $\beta$, the driving torque average value is given by:

$$\overline{T_i} = kl_1 I_m \cos \beta$$  \hspace{1cm} (37.17)$$

and thus, the pointer displacement in Equation 37.16 becomes:

$$\lambda = h \frac{k}{k_s} I_f I_m \cos \beta$$  \hspace{1cm} (37.18)$$

In order to realize a voltmeter, the stationary and moving coils are series connected, and a resistor, with resistance $R$, is also connected in series to the coils. If $R$ is far greater than the resistance of the two coils, and if it is also far greater than the coil inductance, in the frequency operating range of the voltmeter, the rms value of the coils’ currents is given by:

$$I_i = I_m = \frac{U}{R}$$ \hspace{1cm} (37.19)$$

$U$ being the applied voltage rms value. From Equation 37.18, the pointer displacement is therefore given by:

$$\lambda = h \frac{k}{k_s} \frac{U^2}{R^2} = k_s U^2$$  \hspace{1cm} (37.20)$$

Because of Equation 37.20, the voltmeter features a square-law scale, with $k_s$ constant, provided that the coils are carefully designed, and that the coils’ inductance can be neglected with respect to the resistance.
of the coils themselves and the series resistor. This last condition determines the upper limit of the input voltage frequency.

These voltmeters feature good accuracy (their uncertainty can be as low as 0.2% of the full-scale value), with full-scale values up to a few hundred volts, in a frequency range up to 2 kHz.

**Electrostatic Voltmeters**

The action of electrostatic instruments is based on the force exerted between two charged conductors. The conductors behave as a variable plate air capacitor, as shown in Figure 37.6. The moving plate, when charged, tends to move so as to increase the capacitance between the plates. The energy stored in the capacitor, when the applied voltage is \( U \) and the capacitance is \( C \), is given by:

\[
W = \frac{1}{2} C U^2 \quad (37.21)
\]

This relationship is valid both under dc and ac conditions, provided that the voltage rms value \( U \) is considered for ac voltage.

When the moving plate is displaced horizontally by \( ds \), while the voltage is held constant, the capacitor energy changes in order to equal the work done in moving the plate. The resulting force is:

\[
F = \frac{dW}{ds} = \frac{U^2}{2} \frac{dC}{ds} \quad (37.22)
\]

For a rotatable system, Equation 37.21 leads similarly to a resulting torque:

\[
T = \frac{dW}{d\phi} = \frac{U^2}{2} \frac{dC}{d\phi} \quad (37.23)
\]

If the action of a control spring is also considered, both Equations 37.22 and 37.23 show that the balance position of the moving plate is proportional to the square of the applied voltage, and hence electrostatic.
voltmeters have a square-law scale. These equations, along with Equation 37.21, show that these instruments can be used for the measurement of both dc and ac rms voltages. However, the force (or torque) supplied by the instrument schematically represented in Figure 37.6 is generally very weak [2], so that its use is very impractical.

The Electrometer.
A more useful configuration is the quadrant electrometer, shown in Figure 37.7. Four fixed plates realize four quadrants and surround a movable vane suspended by a torsion fiber at the center of the system. The opposite quadrants are electrically connected together, and the potential difference \((U_1 - U_2)\) is applied. The moving vane can be either connected to potential \(U_1\) or \(U_2\), or energized by an independent potential \(U_3\).

Let the zero torque position of the suspension coincide with the symmetrical X-X position of the vane. If \(U_1 = U_2\), the vane does not leave this position; otherwise, the vane will rotate.

Let \(C_1\) and \(C_2\) be the capacitances of quadrants 1 and 2, respectively, relative to the vane. They both are functions of \(\theta\) and, according to Equation 37.23, the torque applied to the vane is given by:

\[
T = \frac{(U_3 - U_1)^2}{2} \frac{dC_1}{d\theta} + \frac{(U_3 - U_2)^2}{2} \frac{dC_2}{d\theta} \tag{37.24}
\]
Since the vane turns out of one pair of quadrants as much as it turns into the other, the variations of $C_1$ and $C_2$ can be related by:

$$\frac{dC_1}{d\vartheta} = \frac{dC_2}{d\vartheta} = k_i$$

(37.25)

Taking into account the suspension restraining torque $T_r = k_2 \vartheta$, the balance position can be obtained by Equations 37.24 and 37.25 as:

$$\vartheta = \frac{k_1}{2k_2} \left[ (U_3 - U_2)^2 - (U_3 - U_1)^2 \right]$$

(37.26)

If the vane potential $U_3$ is held constant, and is large compared to the quadrant potentials $U_1$ and $U_2$, Equation 37.26 can be simplified as follows:

$$\vartheta = \frac{k_1}{k_2} U_3 \left( U_1 - U_2 \right)$$

(37.27)

Equation 37.27 shows that the deflection of the vane is directly proportional to the voltage difference applied to the quadrants. This method of use is called the heterostatic method.

If the vane is connected to quadrant 1, $U_3 = U_1$ follows, and Equation 37.26 becomes

$$\vartheta = \frac{k_1}{2k_2} (U_1 - U_2)^2$$

(37.28)

Equation 37.28 shows that the deflection of the vane is proportional to the square of the voltage difference applied to the quadrants, and hence this voltmeter has a square-law scale. This method of use is called the idiostatic method, and is suitable for the direct measurement of dc and ac voltages without an auxiliary power source.

The driving torque of the electrometer is extremely weak, as in all electrostatic instruments. The major advantage of using this kind of meter is that it allows for the measurement of dc voltages without drawing current by the voltage source under test. Now, due to the availability of operational amplifiers with extremely high input impedance, they have been almost completely replaced by electronic meters with high input impedance.

**Electronic Voltmeters**

Electronic meters process the input signal by means of semiconductor devices in order to extract the information related to the required measurement [3, 4]. An electronic meter can be basically represented as a three-port element, as shown in Figure 37.8.

The input signal port is an input port characterized by high impedance, so that the signal source has very little load. The measurement result port is an output port that provides the measurement result (in either an analog or digital form, depending on the way the input signal is processed) along with the power needed to energize the device used to display the measurement result. The power supply port is an input port which the electric power required to energize the meter internal devices and the display device flows through.

One of the main characteristics of an electronic meter is that it requires an external power supply. Although this may appear as a drawback of electronic meters, especially where portable meters are...
concerned, note that this way, the energy required for the measurement is no longer drawn from the signal source.

The high-level performance of modern electronic devices yields meters that are as accurate (and sometime even more accurate) as the most accurate electromechanical meters. Because they do not require the extensive use of precision mechanics, they are presently less expensive than electromechanical meters, and are slowly, but constantly, replacing them in almost all applications.

Depending on the way the input signal is processed, electronic meters are divided into analog and digital meters. Analog meters attain the required measurement by analog, continuous-time processing of the input signal. The measurement result can be displayed both in analog form using, for example, an electromechanical meter; or in digital form by converting the analog output signal into digital form. Digital meters attain the required measurement by digital processing of the input signal. The measurement result is usually displayed in digital form. Note that the distinction between analog and digital meters is not due to the way the measurement result is displayed, but to the way the input signal is processed.

**Analog Voltmeters**

An electronic analog voltmeter is based on an electronic amplifier and an electromechanical meter to measure the amplifier output signal. The amplifier operates to make a dc current, proportional to the input quantity to be measured, flow into the meter. This meter is hence a dc moving-coil milliammeter.

Different full-scale values can be obtained using a selectable-ratio voltage divider if the input voltage is higher than the amplifier dynamic range, or by selecting the proper amplifier gain if the input voltage stays within the amplifier dynamic range.

The main features of analog voltmeters are high input impedance, high possible gain, and wide possible bandwidth for ac measurements. The relative measurement uncertainty can be lower than 1% of full-scale value. Because of these features, electronic analog voltmeters can have better performance than the electromechanical ones.

**Dc Analog Voltmeters.**

Figure 37.9 shows the circuit for an electronic dc analog voltmeter. Assuming that the operational amplifier exhibits ideal behavior, current \( I_m \) flowing in the milliammeter \( A \) is given by:

\[
I_m = I_o + I_z = \frac{U_o}{R_o} + \frac{U_o}{R_2} = -U_o \frac{R_2}{R_1} \frac{R_z + R_o}{R_z R_o} = -U_o \left( 1 + \frac{R_o}{R_z} \right)
\]

(37.29)

If \( R_z = R_o \), and the same resistances are far greater than \( R_o \), Equation 37.29 can be simplified to:

\[
I_m = -\frac{U_o}{R_o}
\]

(37.30)
Equation 37.30 shows that the milliammeter reading is directly proportional to the input voltage through resistance \( R_0 \) only. This means that, once the milliammeter full-scale value is set, the voltmeter full-scale value can be changed, within the dynamic range of the amplifier, by changing the \( R_0 \) value. This way, the meter full-scale value can be changed without changing its input impedance.

Rectifier-Based ac Analog Voltmeters.

Analog meters for ac voltages can be obtained starting from the dc analog voltmeters, with a rectifying input stage. Figure 37.10 shows how the structure in Figure 37.9 can be modified in order to realize an ac voltmeter.

Because of the high input impedance of the electronic amplifier, \( i_2(t) = 0 \), and the current \( i_m(t) \) flowing in the milliammeter A is the same as current \( i_o(t) \) flowing in the load resistance. Since the amplifier is connected in a voltage-follower configuration, the output voltage is given by:

\[
u_o(t) = u_i(t)
\]  

(37.31)

Due to the presence of the input diode, current \( i_m(t) \) is given by:

\[
i_m(t) = \frac{u_i(t)}{R_0}
\]  

(37.32)

when \( u_i(t) > 0 \), and
when \( u(t) \leq 0 \). If \( u(t) \) is supposed to be a sine wave, the waveform of \( i_m(t) \) is shown in Figure 37.11.

The dc moving-coil milliammeter measures the average value \( I_m \) of \( i_m(t) \), which, under the assumption of sinusoidal signals, is related to the rms value \( U_i \) of \( u(t) \) by:

\[
I_m = \frac{2\sqrt{2}U_i}{\pi R_o}
\]  

(37.34)

The performance of the structure in Figure 37.10 can be substantially improved by considering the structure in Figure 37.12 which realizes a full-wave rectifier. Because of the presence of diodes \( D_1 \) and \( D_2 \), the output of amplifier A1 is given by:

\[
u(t) = \begin{cases} 
-u(t) & \text{for } u(t) \geq 0 \\
0 & \text{for } u(t) < 0
\end{cases}
\]  

(37.35)

where \( u(t) \) is the circuit input voltage.
If capacitor $C$ is supposed to be not connected, amplifier $A_2$ output voltage is:

$$ u_2(t) = -\left[ u_1(t) + 2u_i(t) \right] $$

(37.36)

which gives:

$$ u_2(t) = \begin{cases} 
  u_1(t) & \text{for } u_i(t) \geq 0 \\
  -u_1(t) & \text{for } u_i(t) < 0 
\end{cases} $$

(37.37)

thus proving that the circuit in Figure 37.12 realizes a full-wave rectifier.

If $u_i(t)$ is a sine wave, the waveforms of $u_i(t)$, $u_1(t)$ and $u_2(t)$ are shown in Figure 37.13.

Connecting capacitor $C$ in the feedback loop of amplifier $A_2$ turns it into a first-order low-pass filter, so that the circuit output voltage equals the average value of $u_o(t)$:

$$ \bar{U}_o = \left| u_i(t) \right| $$

(37.38)

In the case of sinusoidal input voltage with rms value $U_i$, the output voltage is related to this rms value by:

$$ \bar{U}_o = \frac{2\sqrt{2}}{\pi} U_i $$

(37.39)

$\bar{U}_o$ can be measured by a dc voltmeter.

Both meters in Figures 37.10 and 37.12 are actually average detectors. However, due to Equations 37.34 and 37.39, their scale can be labeled in such a way that the instrument reading gives the rms value of the input voltage, provided it is sinusoidal. When the input voltage is no longer sinusoidal, an error arises that depends on the signal form factor.

True rms Analog Voltmeters.
The rms value $U_i$ of a periodic input voltage signal $u_i(t)$, with period $T$, is given by:

$$ U_i = \sqrt{\frac{1}{T} \int_0^T u_i^2(t) \, dt} $$

(37.40)
The electronic circuit shown in Figure 37.14 provides an output signal $U_o$ proportional to the squared rms value of the input signal $u_i(t)$. The circuit section between nodes 1 and 2 is a full-wave rectifier. Hence, node 2 potential is given by:

$$u_2(t) = |u_1(t)| \quad (37.41)$$

The circuit section between nodes 2 and 4 is a log multiplier. Because of the logarithmic characteristic of the feedback path due to the presence of $T_1$ and $T_2$, node 3 potential is given by:

$$u_3(t) = 2k_1 \log[u_2(t)] = k_1 \log[u_i^2(t)] = k_1 \log\left[\int_0^T u_i^2(t) dt\right] = k_1 \log[u_i^2(t)] \quad (37.42)$$

and, due to the presence of $T_3$, the current flowing in node 4 is given by:

$$i_4(t) = k_2 \exp[u_3(t)] = k_2 u_i^2(t) \quad (37.43)$$

The circuit section after node 4 is a low-pass filter that extracts the dc component of the input signal. Therefore, the circuit output voltage is given by:

$$U_o = \frac{k}{T} \int_0^T u_i^2(t) dt = kU_i^2 \quad (37.44)$$

thus providing an output signal proportional to the squared rms value of the input signal $u_i(t)$ in accordance with Equation 37.40. Quantities $k_1$, $k_2$, and $k$ depend on the values of the elements in the circuit in Figure 37.14. Under circuit operating conditions, their values can be considered constant, so that $k_1$, $k_2$, and $k$ can be considered constant also.

If carefully designed, this circuit can feature an uncertainty in the range of ±1% of full scale, for signal frequencies up to 100 kHz.

**Digital Voltmeters**

A digital voltmeter (DVM) attains the required measurement by converting the analog input signal into digital, and, when necessary, by discrete-time processing of the converted values. The measurement result is presented in a digital form that can take the form of a digital front-panel display, or a digital output signal. The digital output signal can be coded as a decimal BCD code, or a binary code.
The main factors that characterize DVMs are speed, automatic operation, and programmability. In particular, they presently offer the best combination of speed and accuracy if compared with other available voltage-measuring instruments. Moreover, the capability of automatic operations and programmability make DVMs very useful in applications where flexibility, high speed and computer controllability are required. A typical application field is therefore that of automatically operated systems.

When a DVM is directly interfaced to a digital signal processing (DSP) system and used to convert the analog input voltage into a sequence of sampled values, it is usually called an analog-to-digital converter (ADC).

DVMs basically differ in the following ways: (1) number of measurement ranges, (2) number of digits, (3) accuracy, (4) speed of reading, and (5) operating principle.

The basic measurement ranges of most DVMs are either 1 V or 10 V. It is however possible, with an appropriate preamplifier stage, to obtain full-scale values as low as 0.1 V. If an appropriate voltage divider is used, it is also possible to obtain full-scale values as high as 1000 V.

If the digital presentation takes the form of a digital front-panel display, the measurement result is presented as a decimal number, with a number of digits that typically ranges from 3 to 6. If the digital representation takes the form of a binary-coded output signal, the number of bits of this representation typically ranges from 8 to 16, though 18-bit ADCs are available.

The accuracy of a DVM is usually correlated to its resolution. Indeed, assigning an uncertainty lower than the 0.1% of the range to a three-digit DVM makes no sense, since this is the displayed resolution of the instrument. Similarly, a poorer accuracy makes the three-digit resolution quite useless. Presently, a six-digit DVM can feature an uncertainty range, for short periods of time in controlled environments, as low as the 0.0015% of reading or 0.0002% of full range.

The speed of a DVM can be as high as 1000 readings per second. When the ADC is considered, the conversion rate is taken into account instead of the speed of reading. Presently, the conversion rate for 12-bit, successive approximation ADCs can be on the order of 10 MHz. It can be in the order of 100 MHz for lower resolution, flash ADCs [5].

DVMs can be divided into two main operating principle classes: the integrating types and the nonintegrating types [3]. The following sections give an example for both types.

Dual Slope DVM.

Dual slope DVMs use a counter and an integrator to convert an unknown analog input voltage into a ratio of time periods multiplied by a reference voltage. The block diagram in Figure 37.15 shows this operating principle. The switch S1 connects the input signal to the integrator for a fixed period of time $t_f$. If the input voltage is positive and constant, $u_i(t) = U_i > 0$, the integrator output represents a negative-slope ramp signal (Figure 37.16). At the end of $t_f$, S1 switches and connects the output of the voltage reference $U_R$ to the integrator input. The voltage reference output is negative for a positive input voltage. The integrator output starts to increase, following a positive-slope ramp (Figure 37.16). The process stops when the ramp attains the 0 V level, and the comparator allows the control logic to switch S1 again. The period of time $t_v$ the ramp takes to increase to 0 V is variable and depends on the ramp peak value attained during period $t_f$.

The relationship between the input voltage $U_i$ and the time periods $t_v$ and $t_f$ is given by:

$$
\frac{1}{RC} \int_0^{t_v} U_i dt = \frac{t_v}{RC} U_R
$$

that, for a constant input voltage $U_i$, leads to:

$$
U_i = U_R \frac{t_v}{t_f}
$$

(37.46)
Since the same integrating circuit is used, errors due to comparator offset, capacitor tolerances, long-term counter clock drifts, and integrator nonlinearities are eliminated. High resolutions are therefore possible, although the speed of reading is low (in the order of milliseconds).

Slowly varying voltages can be also measured by dual slope DVMs. However, this requires that the input signal does not vary for a quantity greater than the DVM resolution during the reading time. For high-resolution DVMs, this limits the DVM bandwidth to a few hertz.
Successive Approximation ADC.

The successive approximation technique represents the most popular technique for the realization of ADCs. Figure 37.17 shows the block diagram of this type of converter. The input voltage is assumed to have a constant value $U_i$ and drives one input of the comparator. The other comparator’s input is driven by the output of the digital-to-analog converter (DAC), which converts the binary code provided by the successive approximation register (SAR) into an analog voltage. Let $n$ be the number of bits of the converter, $U_R$ the voltage reference output, and $C$ the code provided by the SAR. The DAC output voltage is then given by:

$$U_c = \frac{C}{2^n} U_R$$  \hspace{1cm} (37.47)

When the conversion process starts, the SAR most significant bit (MSB) is set to logic 1. The DAC output, according to Equation 37.47, is set to half the reference value, and hence half the analog input full-scale range. The comparator determines whether the DAC output is above or below the input signal. The comparator output controls the SAR in such a way that, if the input signal is above the DAC output, as shown in Figure 37.18, the SAR MSB is retained and the next bit is set to logic 1.

If now the input signal is below the DAC output (Figure 37.18), the last SAR bit set to logic 1 is reset to logic 0, and the next one is set to logic 1. The process goes on until the SAR least significant bit (LSB) has been set. The entire conversion process takes time $t_c = nT_c$, where $T_c$ is the clock period. At the end of conversion, the SAR output code represents the digitally converted value of the input analog voltage $U_i$.

According to Equation 37.47, the ADC resolution is $U_R/2^n$, which corresponds to 1 LSB. The conversion error can be kept in the range $\pm$½ LSB. Presently, a wide range of devices is available, with resolution from 8 to 16 bits, and conversion rates from 100 µs to below 1 µs.

Varying voltages can be sampled and converted into digital by the ADC, provided the input signal does not vary by a quantity greater than $U_R/2^n$ during the conversion period $t_c$. The maximum frequency of an input sine wave that satisfies this condition can be readily determined starting from given values of $n$ and $t_c$.

Let the input voltage of the ADC be an input sine wave with peak-to-peak voltage $U_{pp} = U_R$ and frequency $f$. Its maximum variation occurs at the zero-crossing time and, due to the short conversion period $t_c$, is given by $2\pi ft_c U_{pp}$. To avoid conversion errors, it must be:

$$2\pi f t_c U_{pp} \leq \frac{U_R}{2^n}$$  \hspace{1cm} (37.48)

Since $U_{pp} = U_R$ is assumed, this leads to:

$$f \leq \frac{1}{2^n 2\pi t_c}$$  \hspace{1cm} (37.49)
If $t_c = 1 \mu s$ and $n = 12$, Equation 37.49 leads to $f \leq 38.86$ Hz. However, ADCs can still be employed with input signals whose frequency exceeds the value given by Equation 37.49, provided that a Sample and Hold circuit is used to keep the input voltage constant during the conversion period.

The Sample and Hold circuit is shown in Figure 37.19. When the electronic switch $S$ is closed, the output voltage $u_o(t)$ follows the input voltage $u_i(t)$. When switch $S$ is open, the output voltage is the same as the voltage across capacitor $C$, which is charged at the value assumed by the input voltage at the time the switch was opened. Due to the high input impedance of the operational amplifier $A_2$, if a suitable value is chosen for capacitor $C$, its discharge transient is slow enough to keep the variation of the output voltage below the ADC resolution.

**Ac Digital Voltmeters.**

True rms ac voltimeters with digital reading can be obtained using an electronic circuit like the one in Figure 37.14 to convert the rms value into a dc voltage signal, and measuring it by means of a DVM.
However, this structure cannot actually be called a digital structure, because the measurement is attained by means of analog processing of the input signal.

A more modern approach, totally digital, is shown in Figure 37.20. The input signal \( u_i(t) \) is sampled at constant sampling rate \( f_s \) and converted into digital by the ADC. The digital samples are stored in the memory of the digital signal processor (DSP) and then processed in order to evaluate Equation 37.40 in a numerical way. Assuming that the input signal is periodic, with period \( T \) and its frequency spectrum is upper limited by harmonic component of order \( N \), the sampling theorem is satisfied if at least \((2N + 1)\) samples are taken over period \( T \) in such a way that \((2N + 1)T_s = T, T_s = 1/f_s\), being the sampling period \([6, 7]\). If \( u_i(kT_s) \) is the \( k \)th sample, the rms value of the input signal is given by, according to Equation 37.40:

\[
U^2 = \frac{1}{2N+1} \sum_{k=0}^{2N} u^2(kT_s)
\]

(37.50)

This approach can feature a relative uncertainty as low as ±0.1% of full scale, with an ADC resolution of 12 bits. The instrument bandwidth is limited to half the sampling frequency, according to the sampling theorem. When modern ADCs and DSPs are employed, a 500-kHz bandwidth can be obtained. Wider bandwidths can be obtained, but with a lower ADC resolution, and hence with a lower accuracy.

Frequency Response of ac Voltmeters.

When the frequency response of ac voltmeters is taken into account, a distinction must be made between the analog voltmeters (both electromechanical and electronic) and digital voltmeters, based on DSP techniques.

The frequency response of the analog meters is basically a low-pass response, well below 1 kHz for most electromechanical instruments, and up to hundreds of kilohertz for electronic instruments.

When digital, DSP-based meters are concerned, the sampling theorem and aliasing effects must be considered. To a first approximation, the frequency response of a digital meter can be considered flat as long as the frequency-domain components of the input signal are limited to a frequency band narrower than half the sampling rate. If the signal components exceed this limit (the so-called Nyquist frequency), the aliasing phenomenon occurs [6]. Because of this phenomenon, the signal components at frequencies higher than half the sampling rate are folded over the lower frequency components, changing them. Large measurement errors occur under this situation.

To prevent the aliasing, a low-pass filter must be placed at the input stage of any digital meter. The filter cut-off frequency must ensure that all frequency components above half the sampling rate are negligible. If the low-pass, anti-aliasing filter is used, the digital DSP-based meters feature a low-pass frequency response also.

37.2 Oscilloscope Voltage Measurement

Jerry Murphy

Engineers, scientists, and other technical professionals around the world depend on oscilloscopes as one of the primary voltage measuring instruments. This is an unusual situation because the oscilloscope is not the most accurate voltage measuring instrument usually available in the lab. It is the graphical nature of the oscilloscope that makes it so valued as a measurement instrument — not its measurement accuracy.

The oscilloscope is an instrument that presents a graphical display of its input voltage as a function of time. It displays voltage waveforms that cannot easily be described by numerical methods. For example, the output of a battery can be completely described by its output voltage and current. However, the output of a more complex signal source needs additional information such as frequency, duty cycle, peak-to-peak amplitude, overshoot, preshoot, rise time, fall time, and more to be completely described. The oscilloscope, with its graphical presentation of complex waveforms, is ideally suited to this task. It is often described as the “screwdriver of the electronic engineer” because the oscilloscope is the most fundamental tool that technical professionals apply to the problem of trying to understand the details of the operation of their electronic circuit or device. So, what is an oscilloscope?

The oscilloscope is an electronic instrument that presents a high-fidelity graphical display of the rapidly changing voltage at its input terminals.

The most frequently used display mode is voltage vs. time. This is not the only display that could be used, nor is it the display that is best suited for all situations. For example, the oscilloscope could be called on to produce a display of two changing voltages plotted one against the other, such as a Lissajous display. To accurately display rapidly changing signals, the oscilloscope is a high bandwidth device. This means that it must be capable of displaying the high-order harmonics of the signal being applied to its input terminals in order to correctly display that signal.

The Oscilloscope Block Diagram

The oscilloscope contains four basic circuit blocks: the vertical amplifier, the time base, the trigger, and the display. This section treats each of these in a high-level overview. Many textbooks exist that cover the details of the design and construction of each of these blocks in detail [1]. This discussion will cover these blocks in enough detail so that readers can construct their own mental model of how their operation affects the application of the oscilloscope for their voltage measurement application. Most readers of this book have a mental model of the operation of the automatic transmission of an automobile that is sufficient for its successful operation but not sufficient for the overhaul or redesign of that component. It is the goal of this section to instill that level of understanding in the operation of the oscilloscope. Those readers who desire a deeper understanding will get their needs met in later sections.

Of the four basic blocks of the oscilloscope, the most visible of these blocks is the display with its cathode-ray tube (CRT). This is the component in the oscilloscope that produces the graphical display of the input voltage and it is the component with which the user has the most contact. Figure 37.21 shows the input signal is applied to the vertical axis of a cathode ray tube. This is the correct model for an analog oscilloscope but it is overly simplified in the case of the digital oscilloscope. The important thing to learn from this diagram is that the input signal will be operated on by the oscilloscope's vertical axis circuits so that it can be displayed by the CRT. The differences between the analog and digital oscilloscope are covered in later sections.
The vertical amplifier conditions the input signal so that it can be displayed on the CRT. The vertical amplifier provides controls of volts per division, position, and coupling, allowing the user to obtain the desired display. This amplifier must have a high enough bandwidth to ensure that all of the significant frequency components of the input signal reach the CRT.

The trigger is responsible for starting the display at the same point on the input signal every time the display is refreshed. It is the stable display of a complex waveform that allows the user of an oscilloscope to make judgments about that waveform and its implications as to the operation of the device under test.

The final piece of the simplified block diagram is the time base. This circuit block is also known as the horizontal system in some literature. The time base is the part of the oscilloscope that causes the input signal to be displayed as a function of time. The circuitry in this block causes the CRT beam to be deflected from left to right as the input signal is being applied to the vertical deflection section of the CRT. Controls for time-per-division and position (or delay) allow the user of the oscilloscope to adjust the display for the most useful display of the input signal. The time-per-division controls of most oscilloscopes provide a wide range of values, ranging from a few nanoseconds (10⁻⁹ s) to seconds per division. To get a feeling for the magnitude of the dynamic range of the oscilloscope's time base settings, keep in mind that light travels about 1 m in 3 ns.

The Oscilloscope As a Voltage Measurement Instrument

That the oscilloscope's vertical axis requires a wide bandwidth amplifier and its time base is capable of displaying events that are as short as a few nanoseconds apart, indicates that the oscilloscope can display rapidly changing voltages. Voltmeters, on the other hand, are designed to give their operator a numeric readout of steady-state or slowly changing voltages. Voltmeters are not well suited for displaying voltages that are changing levels very quickly. This can be better understood by examination of the operation of a voltmeter as compared to that of an oscilloscope. The analog voltmeter uses the magnetic field produced by current flowing through a coil to move the pointer against the force of a spring. This nearly linear deflection of the voltmeter pointer is calibrated by applying known standard voltages to its input.
Therefore, if a constant voltage is applied to the coil, the pointer will move to a point where the magnetic force being produced by the current flowing in its coil is balanced by the force of the spring. If the input voltage is slowly changing, the pointer will follow the changing voltage. This mechanical deflection system limits the ability of this measurement device to the measurement of steady-state or very low-frequency changes in the voltage at its input terminals. Higher-frequency voltmeters depend on some type of conversion technique to change higher frequencies to a dc signal that can be applied to the meter’s deflection coil. For example, a diode is used to rectify ac voltages to produce a dc voltage that corresponds to the average value of the ac voltage at the input terminals in average responding ac voltmeters.

The digital voltmeter is very much like the analog meter except that the mechanical displacement of the pointer is replaced with a digital readout of the input signal. In the case of the digital voltmeter, the input signal is applied to an analog-to-digital converter (ADC) where it is compared to a reference voltage and digitized. This digital value of the input signal is then displayed in a numerical display. The ADC techniques applied to voltmeters are designed to produce very accurate displays of the same signals that were previously measured with analog meters. The value of a digital voltmeter is its improved measurement accuracy as compared to that of its analog predecessors.

The oscilloscope will display a horizontal line displaced vertically from its zero-voltage level when a constant, or dc voltage is applied to its input terminals. The magnitude of this deflection of the oscilloscope’s beam vertically from the point where it was operating with no input being applied is how the oscilloscope indicates the magnitude of the dc level at its input terminals. Most oscilloscopes have a graticule as a part of their display and the scope’s vertical axis is calibrated in volts per division of the graticule. As one can imagine, this is not a very informative display of a dc level and perhaps a voltmeter with its numeric readout is better suited for such applications.

There is more to the scope–voltmeter comparison than is obvious from the previous discussion. That the oscilloscope is based on a wide-bandwidth data-acquisition system is the major difference between these two measurement instruments. The oscilloscope is designed to produce a high fidelity display of rapidly changing signals. This puts additional constraints on the design of the oscilloscope’s vertical system that are not required in the voltmeter. The most significant of these constraints is that of a constant group delay. This is a rather complex topic that is usually covered in network analysis texts. It can be easily understood if one realizes the effect of group delay on a complex input signal.

Figure 37.22 shows such a signal. The amplitude of this signal is a dc level and the rising edge is made up of a series of high-frequency components. Each of these high-frequency components is a sine wave of specific amplitude and frequency. Another example of a complex signal is a square wave with a frequency of 10 MHz. This signal is made up of a series of odd harmonics of that fundamental frequency. These harmonics are sine waves of frequencies of 10 MHz, 30 MHz, 50 MHz, 70 MHz, etc. So, the oscilloscope must pass all of these high-frequency components to the display with little or no distortion. Group delay is the measure of the propagation time of each component through the vertical system. A constant group delay means that each of these components will take the same amount of time to propagate through the vertical system to the CRT, independent of their frequencies. If the higher-order harmonics take more or less time to reach the scope’s deflection system than the lower harmonics, the resulting display will be a distorted representation of the input signal. Group delay (in seconds) is calculated by taking the first derivative of an amplifier’s phase-vs.-frequency response (in radians/(l/s)). If the amplifier has a linearly increasing phase shift with frequency, the first derivative of its phase response will be a horizontal line corresponding to the slope of the phase plot (in seconds). Amplifier systems that have a constant group delay are known as Gaussian amplifiers. They have this name because their pass band shape resembles that of the bell curve of a Gaussian distribution function (Figure 37.23). One would think that the oscilloscope’s vertical amplifier should have a flat frequency response, but this is not the case because such amplifiers have nonconstant group delay [1].

The oscilloscope’s bandwidth specification is based on the frequency where the vertical deflection will be –3 dB (0.707) of the input signal. This means that if a constant 1-V sine wave is applied to the oscilloscope’s input, and the signal’s frequency is adjusted to higher and higher frequencies, the oscilloscope’s bandwidth will be that frequency where its display of the input signal has been reduced to be
Noticable errors in amplitude measurements will start at 20% of the scope’s bandwidth. The oscilloscope’s error-free display of complex waveforms gives it poor voltage accuracy. For the measurement of dc and single frequency signals such as sine waves, other instruments can produce more accurate measurements.

**Conclusion:**

The voltmeter makes the most accurate measurements of voltages that are dc, slowly changing, or can be converted to a dc analog of their ac content. The oscilloscope is not the most accurate voltage measurement instrument, but it is well suited to measurements of voltages that are changing very slowly.

![Figure 37.22](image1.png)

**FIGURE 37.23** The Gaussian frequency response of the oscilloscope’s vertical system which is not flat in its pass band. Amplitude measurements made at frequencies greater than 20% of the scope’s bandwidth will be in error.

0.707 V. Noticable errors in amplitude measurements will start at 20% of the scope’s bandwidth. The oscilloscope’s error-free display of complex waveforms gives it poor voltage accuracy. For the measurement of dc and single frequency signals such as sine waves, other instruments can produce more accurate measurements.

**Conclusion:** The voltmeter makes the most accurate measurements of voltages that are dc, slowly changing, or can be converted to a dc analog of their ac content. The oscilloscope is not the most accurate voltage measurement instrument, but it is well suited to measurements of voltages that are changing very slowly.
rapidly as a function of time. Oscilloscopes are the instrument of choice for observing and characterizing these complex voltages.

**Analog or Digital**

The world of oscilloscopes is divided into two general categories: analog and digital. The first oscilloscopes were analog. These products are based on the direct-view vector cathode-ray tube (DVVCRT or CRT for short). The analog oscilloscope applies the input signal to the vertical deflection plates of the CRT where it causes the deflection of a beam of high-energy electrons moving toward the phosphor-coated faceplate. The electron beam generates a lighted spot where it strikes the phosphor. The intensity of the light is directly related to the density of the electrons hitting a given area of the phosphor. Because this analog operation is not based on any digitizing techniques, most people have little trouble creating a very accurate and simple mental model in their minds of its operation.

The analog oscilloscope produces a display of the input signal that is bright and easy to see under most conditions. It can also contain as many as 16 shades of gray-scale information. This means that an event that occurs less frequently will appear at a lower intensity in the display than another event that occurs more frequently. This oscilloscope does not produce a continuous display of the input signal. It is blind during retrace and trigger hold-off times. Because the display depends on the production of visible light from the phosphor being excited by an electron beam, the display must be refreshed frequently. This makes the analog oscilloscope a low-dead-time display system that can follow rapidly changing signals. Also, there is little lag time in front panel control settings.

The analog oscilloscope is not without its shortcomings. The strength of the analog oscilloscope is its CRT, but this is also the source of its weaknesses. The biggest problem with analog scopes is their dependence on a display that is constantly being refreshed. This means that these scopes do not have any waveform storage. If the input signal fails to repeat frequently, the display will simply be a flash of light when the beam sweeps by the phosphor. If the signal's repetition rate falls below 100 Hz, the display will flicker annoyingly. Figure 37.24 shows a plot of the range of an input signal's repetition frequency range from a single-shot event to the full bandwidth of a scope vs. the scope's sweep speeds. The result is a map of the scope's operational area. Figure 37.24 shows that the analog oscilloscope fails to map onto the full range of possible input signals and sweep speeds.

Another problem of the analog oscilloscope is its inability to display information ahead of its trigger. This is a problem in applications where the only suitable trigger is at the end of the event of interest. Another limitation of analog scopes is their timing accuracy. The time base of the analog scope is based on the linearity of a voltage ramp. There are other sources of errors in the analog oscilloscope's horizontal axis, but the sweep nonlinearity is the major contributor. This results in these scopes having a timing accuracy of typically ±3% of their full-scale setting. Therefore, if the time base is set to 100 ns/div, in order to view a 100-ns wide pulse, the full scale will be 1000 ns or 1 μs. The accuracy of this pulse width measurement will be ±30 ns or ±30% of the pulse width!

The digital oscilloscope or digital storage oscilloscope (DSO) differs from its analog counterpart in that the input signal is converted to digital data and therefore it can be managed by an embedded microprocessor. The waveform data can have correction factors applied to remove errors in the scope's acquisition system and can then be stored, measured, and/or displayed. That the input signal is converted from analog to digital and manipulations are performed on it by a microprocessor results in people not having a good mental model of the digital oscilloscope's operation. This would not be a problem except for the fact that the waveform digitizing process is not totally free from errors, and a lack of a correct mental model of the scope's operation on the part of its user can increase the odds of a measurement error. To make matters worse, various manufacturers of these products make conflicting claims, making it easy to propagate incorrect mental models of the digital scope's operation. It is the intention of this presentation to give the information needed to create a mental model of the operation of these devices that will enable the user to perform error-free measurements with ease.
The digital storage oscilloscope offers many advantages over its analog counterpart. The first is accuracy. The voltage measurement accuracy of the digital oscilloscope is better than that of an analog scope because the microprocessor can apply correction factors to the data to correct for errors in the calibration of the scope's vertical system. The timing accuracy of a digital oscilloscope is an order of magnitude better than that of an analog scope. The digital scope can store the waveform data for comparison to other test results or uploading to a computer for analysis or project documentation. The digital oscilloscope does not depend on the input signal being continuously updated to produce an easily viewable display. A single-shot event is displayed at the same brightness level as a signal that repeats in time periods corresponding to the full bandwidth of the scope.

The disadvantages of the digital oscilloscope are its more complex operation, aliasing, and display performance. The analog-to-digital conversion process is used to convert the input signal into a series of discrete values, or samples, uniformly spaced in time, which can be stored in memory. Voltage resolution is determined by the total number of codes that can be produced. A larger number permits a smoother and more accurate reproduction of the input waveform but increases both the cost and difficulty in achieving a high sample frequency. Most digital oscilloscopes provide 8-bit resolution in their ADC. As the ADC's sampling speed is increased, the samples will be closer together, resulting in smaller gaps in the waveform record.

All digital scopes are capable of producing an aliased display. Some models are more prone to this problem than others, but even the best will alias under the right conditions. An alias is a lower frequency false reproduction of the input signal resulting from under-sampling, i.e., sampling less than the Nyquist frequency. The display of the digital scope is based on computer display technology. This results in a display that is very bright and easy to see, even under conditions where an analog scope would have difficulty in producing a viewable display. The disadvantage of the digital scope's display is its lower...
horizontal resolution. Most of the scopes on the market have a raster scan display with a resolution of 500 lines, less than half the resolution of an analog scope's display. This is not a problem in most applications. It could become a factor where very complex waveforms, such as those found in TV systems, are being analyzed. Many digital scopes have display systems that exhibit large dead- or blind-times. Scopes based on a single CPU will be able to display their waveform data only after the CPU has finished all of its operations. This can result a display that is unresponsive to front panel control inputs as well as not being able to follow changes in the input signal.

Table 37.2 shows that both analog and digital oscilloscopes have relative advantages and disadvantages. All the major producers of oscilloscopes are pushing the development of digital scopes in an attempt to overcome their disadvantages. All the major producers of these products believe that the future is digital. However, a few manufacturers produce scopes that are both analog and digital. These products appear to have the best of both worlds; however, they have penalties with respect to both cost and complexity of operation.

One of the driving forces making scope manufacturers believe that the future of the digital oscilloscope is bright is that modern electronic systems are becoming ever more digital in nature. Digital systems place additional demands on the oscilloscope that exceed the capabilities of the analog scope. For example, often in digital electronic systems, there is a need to view fast events that occur at very slow or infrequent rates. Figure 37.24 shows that these events fail to be viewable on analog scopes. Another common problem with digital systems is the location of trigger events. Often the only usable trigger is available at the end of the event being viewed. Analog scopes can only display events that occur after a trigger event. The rapid growth of digital electronics that in the late 1990s is being attributed to the lowering of the cost of single-chip microcontrollers. These devices, which contain a complete microprocessor on one integrated circuit, are responsible for the "electronics everywhere" phenomenon, where mechanical devices are becoming electronic as well as those devices that were previously electrical in nature. In 1996, Hewlett Packard introduced a new class of oscilloscope designed to meet the unique needs of the microcontroller-based applications. This new class of oscilloscope is known as the mixed signal oscilloscope or MSO [2].

**Voltage Measurements**

Voltage measurements are usually based on comparisons of the waveform display to the oscilloscope's graticule. Measurements are made by counting the number of graticule lines between the end-points of the desired measurement and then multiplying that number by the sensitivity setting. This was the only measurement available to most analog scope users, and it is still used by those performing troubleshooting with their digital scope as a time-saving step. (Some late-model analog oscilloscopes incorporate cursors

to enhance their measurement ability.) For example, a waveform that is 4.5 divisions high at a vertical sensitivity of 100 mV/div would be 450 mV high.

Switching the scope's coupling between ac and dc modes will produce a vertical shift in the waveform's position that is a measurement of its dc component. This technique can be applied to either analog or digital scopes. Simply note the magnitude of the change in waveform position and multiply by the channel's sensitivity.

Additional measurements can be performed with an analog oscilloscope but they usually require more skill on the part of the operator. For example, if the operator can determine the location of the top and base of a complex waveform, its amplitude can be measured. Measurements based on percentages can be made using the scope's vernier to scale the waveform so that its top and bottom are 5 divisions apart. Then, each division represents 20% of the amplitude of the waveform being studied. The use of the vernier, which results in the channel being uncalibrated, prevents performance of voltage measurements. Many analog scopes have a red light to warn the operator that the scope is uncalibrated when in vernier mode.

The digital oscilloscope contains an embedded microprocessor that automates the measurement. This measurement automation is based on a histogramming technique, where a histogram of all the voltages levels in the waveform are taken from the oscilloscope's waveform data. The histogram is a plot of the voltage levels in the waveform plotted against the number of samples found at each voltage level. Figure 37.25 shows the histogramming technique being applied to the voltage measurements of complex waveforms.

**Understanding the Specifications**

The oscilloscope's vertical accuracy is one place that a person's mental model of the scope's operation can lead to measurement trouble. For example, the oscilloscope's vertical axis has a frequency response that is not flat across its pass band. However, as noted above, the scope has a Gaussian frequency response.
to produce the most accurate picture of complex signals. This means that the oscilloscope’s accuracy specification of ±3% is a dc-only specification. If one were to attempt to measure the amplitude of a signal whose frequency is equal to the bandwidth of the scope, one would have to add another 29.3% to the error term, for a total error of ±32.3%. This is true for both analog and digital oscilloscopes. This limitation can be overcome by carefully measuring the frequency response of the oscilloscope’s vertical channels. One will need to repeat this process every time the scope is serviced or calibrated, because the various high-frequency adjustments that may need to be made in the scope’s vertical axis will affect the scope’s frequency response. One is probably asking, why don’t the manufacturers do this for me? The answer is twofold. The first is cost, and the second is that this is not the primary application of an oscilloscope. There are other instruments that are much better suited to the measurement of high-frequency signals. The spectrum analyzer would be this author’s first choice.

Additionally, the vertical accuracy is a full-scale specification. This means that at 1 V/div, the full-scale value is typically 8 V. The measurement error for a scope with a ±3% specification under these conditions will be ±0.24 V. If the signal being measured is only 1 V high, the resulting measurement will be ±24% of reading. Check the manual for the scope being used, as some manufacturers will specify full-scale as being 10 or even 10.2 divisions. This will increase the error term because the full-scale term is larger.

In digital oscilloscopes, the vertical accuracy is often expressed as a series of terms. These attempt to describe the analog and digital operations the scope performs on the input signal. Terms might include digitizing resolution, gain, and offset (sometimes called as position). They also might be called out as single and dual cursor accuracies. The single cursor accuracy is a sum of all three terms. In the dual cursor case, where the voltage measurement is made between two voltage cursors, the offset term will cancel out, leaving only the digitizing resolution and gain errors. For example, the Hewlett Packard model 54603B has a single cursor accuracy specification of ±1.2% of full scale, ±0.5% of position value, and a dual cursor specification of ±0.4% of full scale.

**HINT:** Always try to make the voltage measurements on the largest possible vertical and widest possible display of the signal.

The horizontal accuracy specifications of analog and digital scopes are very different; however, both are based on a full-scale value. In the analog scope, many manufacturers limit accuracy specifications to only the center eight divisions of their display. This means that a measurement of a signal that starts or ends in either the first or ninth graticule, will be even more error prone than stated in the scope’s specifications. To the best of this author’s knowledge, this limitation does not apply to digital scopes. The horizontal specifications of digital scopes are expressed as a series of terms. These might include the crystal accuracy, horizontal display resolution, and trigger placement resolution. These can be listed as cursor accuracy. For example, the Hewlett Packard model 54603B has a horizontal cursor accuracy specification of ±0.01% ±0.2% full-scale ±200 ps. In this example, the first term is the crystal accuracy, the second is the display resolution (500 lines), and the final term is twice the trigger placement error. By comparing the analog and digital scopes’ horizontal specifications, it can be seen that in either case, the measurement is more accurate if it can be made at full screen. The digital scope is more accurate than its analog counterpart.

Digital scopes also have acquisition system specifications. Here is another place where the operator’s mental model of the operation of a digital scope can produce measurement errors. All manufacturers of digital scopes specify the maximum sampling speed of their scope’s acquisition system as well as its memory depth and number of bits. The scope’s maximum sampling speed does not apply to all sweep speeds, only memory depth and number of bits applies to all sweep speeds. The scope’s maximum sampling speed applies only to its fastest sweep speeds.

The complexity of the digital scope results from the problem of having to sample the input. There is more to be considered than Nyquist’s Sampling Theorem in the operation of a digital scope. For example, how does the scope’s maximum sampling rate relate to the smallest time interval that the scope can capture and display? A scope that samples at 100 MSa s⁻¹ takes a sample every 10 ns; therefore, in principle, it cannot display any event that is less than 10 ns wide because that event will fall between the samples. In practice, however, this limit can — under certain circumstances — be extended. If the scope is operating in an “equivalent time” or “random repetitive” mode and if the signal is repetitive, even if very
infrequently, the scope will be able to capture any event that is within its vertical system bandwidth. Figure 37.26 shows an infrequently occurring pulse that is 25 ns wide embedded into a data stream being captured and displayed on an oscilloscope with a maximum sampling speed of 20 MSa s\(^{-1}\) (sampling interval of 50 ns). Figure 37.26(b) shows this pulse at a faster sweep speed. An analog scope would produce

\[ \text{48 ns wide glitch at a 15 Hz rate} \]

\[ \text{(a)} \]

\[ \text{Width(1)=48.00ns} \]

\[ \text{(b)} \]
a similar display of this event, with the infrequent event being displayed at a lower intensity than the rest of the trace. Notice that the infrequent event does not break the baseline of the trace.

The correct mental model of the digital scope’s ability to capture signals needs to be based on the scope’s bandwidth, operating modes, and timing resolution. It is the timing resolution that tells the operator how closely spaced the samples can be in the scope’s data record.

The most common flaw in many mental models of the operation of a digital scope is related to its maximum sampling speed specification. As noted, the maximum sampling speed specification applies only to the scope’s fastest sweep speeds. Some scope manufacturers will use a multiplex A/D system that operates at its maximum sampling speed only in single-channel mode. The scope’s memory depth determines its sampling speed at the sweep speed being used for any specific measurement. The scope’s memory depth is always equal to the scope’s horizontal full-scale setting. For scopes with no off-screen memory, this in 10× the time base setting. If the scope has off-screen memory, this must be taken into account. For example, assume that one has two scopes with a maximum sampling speed of 100 MSa s⁻¹. One scope has a memory depth of 5 K points and the other only 1 K. At a sweep speed of 1 μs per division, both scopes will be able to store data into their memory at their full sampling speed, and each will be storing 100 data points per division, for a total of 1000 data points being stored. The scope with the 5 K memory will have a data point in one of every 5 memory locations, and the scope with the 1 K memory will have a data point in every memory location. If one reduces the sweep speed to 5 μs/div, the deeper memory scope will now fill every one of its memory locations with data points separated by 10 ns. The scope with only 1 K of memory would produce a display only 2 divisions wide if its sampling speed is not reduced. Scope designers believe that scope users expect to see a full-length sweep at every sweep speed. Therefore, the 1 K scope must reduce its sampling speed to one sample every 50 ns, or 20 MSa s⁻¹, to be able to fill its memory with a full sweep width of data. This 5:1 ratio of sampling speeds between these two scopes will be maintained as their time bases are set to longer and longer sweeps. For example, at 1 s/div, the 5 K scope will be sampling at 500 samples per second, while the 1 K scope will be sampling at only 100 samples per second. One can determine a scope’s sampling speed for any specific time base setting from Equation 37.51.

\[
S \left(\text{samples/second}\right) = \frac{\text{memory depth (samples)}}{\text{full-scale time base (seconds)}} \quad \text{(37.51)}
\]

or the scope’s maximum sampling speed, whichever is less

One must look closely at the application to determine if a specific scope is best suited to that application. As a rule, the deeper the memory, the faster the scope will be able to sample the signal at any given time base setting. Memory depth is not free. High-speed memory required to be able to store the data out of the scope’s A/D is costly, and deeper memory takes longer to fill, thus reducing the scope’s display update rate. Most scopes that provide memory depths of 20 K or more will also give the user a memory depth selection control so that the user can select between fast and deep. (In 1996, Hewlett Packard Co. introduced two scopes based on an acquisition technology known as MegaZoom (TM) [10] that removes the need for a memory depth control.) A correct mental model for the sampling speed of a digital scope is based on Equation 37.51 and not just on the scope’s maximum performance specifications.

Some digital oscilloscopes offer a special sampling mode known as peak detection. Peak detection is a special mode that has the effect of extending the scope’s sampling speed to longer time records. This special mode can reduce the possibility of an aliased display. The performance of this special mode is specified as the minimum pulse width that the peak detection system can capture. There are several peak detection systems being used by the various manufacturers. Tektronix has an analog-based peak detection system in some of its models, while Hewlett Packard has a digital system in all of its models. Both systems perform as advertised, and they should be evaluated in the lab to see which system best meets one’s needs. There is a down side to peak detection systems and that is that they display high-frequency noise
that might not be within the bandwidth of the system under test. Figure 37.27 shows a narrow pulse being captured by peak detection and being missed when the peak detection is off.

What effect does display dead-time have on the oscilloscope’s voltage measurement capabilities? Display dead-time applies to both analog and digital oscilloscopes, and it is that time when the oscilloscope is not capturing the input signal. This is also a very important consideration in the operation of a digital scope because it determines the scope’s ability to respond to front-panel control commands and to follow
changing waveforms. A digital scope that produces an incorrect display of an amplitude-modulated signal is not following this rapidly changing signal because its display update rate is too low. Sampling speed is not related to display update rate or dead-time. Display dead-time is a function of the scope's ability to process the waveform data from its A/D and plot it on the display. Every major oscilloscope manufacturer has been working on this problem. Tektronix offers a special mode on some of its products known as InstaVu (TM) [4]. This special mode allows these scopes to process up to 400,000 waveforms per second to their display. Hewlett Packard has developed a multiple parallel processor technology [5] in the HP 54600 series of benchtop scopes that provides a high-speed, low dead-time display in a low-cost instrument. These instruments can plot 1,500,000 points per second to their display and they have no dead-time at their slower sweep speeds. LeCroy has been applying the Power PC as an embedded processor for its scopes to increase display throughput. There are other special modes being produced by other vendors, so be sure to understand what these can do before selecting an oscilloscope. Figure 37.28 shows the effect of display update rate on a rapidly changing waveform. An amplitude-modulated signal is displayed with a high-speed display and with the display speed reduced by the use of hold-off.

Triggering

The trigger of the oscilloscope has no direct effect on the scope's ability to measure a voltage except that the trigger does enable the oscilloscope to produce a stable display of the voltage of interest. Ref. [6] presents a thorough discussion of this subject.

Conclusion

The mental model that oscilloscope users have created in their minds of the oscilloscope's operation can be helpful in reducing measurement errors. If the operator's mental model is based on the following facts, measurement errors can be minimized:

- Oscilloscopes have a frequency response that affects measurement accuracy.
- Digital scopes are more accurate than analog scopes.
- Analog scopes do not have continuous displays.
- Oscilloscope accuracy specifications always contain a percent of full-scale term.
- Measurements should be made at the largest possible deflection in order to minimize errors.
- Maximum sampling speed is available only at the scope's fastest sweep speeds.
- Deeper memory depth allows faster sampling at more sweep speeds.
- All digital scopes can produce aliases, some more than others.
- Display dead-time is an important characteristic of digital scopes that is often not specified.
- Display dead-time affects measurement accuracy because it can cause a distorted display.
- The scope with the highest maximum sampling speed specification might not be the most accurate or have the lowest display dead-time.
- The operator must have some knowledge of the signals being measured to be able to make the best possible measurements.

The person who has the mental model of the oscilloscope that takes these factors into account will be able to purchase the scope that is best suited to his/her application and not spend too much money on unnecessary performance. In addition, that person will be able to make measurements that are up to the full accuracy capabilities of the scope.

Selecting the Oscilloscope

There are ten points to consider when selecting an oscilloscope. This author has published a thorough discussion of these points [7] and they are summarized as follows:

1. Analog or Digital? There are a few places where the analog scope might be the best choice, and the reader can make an informed selection based on the information presented here.
2. **How much bandwidth?** This is a place where the person selecting an oscilloscope can save money by not purchasing more bandwidth than is needed. When analog oscilloscopes were the only choice, many people were forced to purchase more bandwidth than they needed because they needed to view infrequent or low repetition signals. High bandwidth analog scopes had brighter CRTs so that they were able to display high-frequency signals at very fast time base settings. At a sweep speed of 5 ns/div, the phosphor is being energized by the electron beam for 50 ns, so the electron beam had

![Diagram](image.png)

**FIGURE 37.28** Display dead-time. The time that an oscilloscope is blind to the input signal has an effect on the scope’s ability to correctly display rapidly changing signals. (a): an amplitude-modulated signal with a high-speed display; (b): the same signal with the dead-time increased by use of hold-off.
to be very high energy to produce a visible trace. This situation does not apply to digital scopes. Now, one needs to be concerned only with the bandwidth required to make the measurement. Figure 37.29 shows the effect of oscilloscope bandwidth on the display of a 50-MHz square wave. The oscilloscope's bandwidth should be \( >2 \times \) the fundamental highest frequency signal to be measured.
The bandwidth of the scope's vertical system can affect the scope's ability to correctly display narrow pulses and to make time interval measurements. Because of the scope's Gaussian frequency response, one can determine its ability to correctly display a transient event in terms of risetime with Equation 37.52.

\[
 t_r = \frac{0.35}{\text{BW}} \tag{37.52}
\]

Therefore, a 100-MHz scope will have a rise time of 3.5 ns. This means that if the scope were to have a signal at its input with zero rise time edges, it would be displayed with 3.5-ns edges.
This will affect the scope's measurements in two ways. First is narrow pulses. Figure 37.30 shows the same 5-ns wide pulse being displayed on oscilloscopes of 500 MHz and 60 MHz bandwidths, and the effect of the lower bandwidth on this event that is closest to the risetime of the slower scope is apparent.

The second is fast time interval measurements. A measurement of signal risetime is an example. The observed risetime on the scope's display is according to Equation 37.53.

\[
 t_{\text{observed}} = \left( t_{\text{signal}}^2 + t_{\text{scope}}^2 \right)^{1/2}
\]

(37.53)

If a 10-ns risetime were to be measured with a 100-MHz scope, one would obtain a measurement of 10.6 ns based on Equation 37.53. The scope would have made this measurement with a 6% reading error before any other factors, such as time base accuracy, are considered.

The scope's risetime should be at least no more than 1/5 of the shortest time interval to be measured. For time interval measurements, this should be >1/10.

3. **How many channels?** Most oscilloscopes in use today are dual-channel models. In addition, there are models described as being 2+2 and four channels. This is one time where 2+2 is not equal to 4. The 2+2 models have limited features on two of their channels and cost less than 4-channel models. Most oscilloscope suppliers will hold the 4-channel description only for models with four full-featured channels, but user should be sure to check that the model under consideration so as to be sure if it is a 4- or 2+2 model. Either of the four channel classes is useful for applications involving the testing and development of digital-based systems where the relationship of several signals must be observed.

Hewlett Packard introduced a new class of oscilloscopes that is tailored for the applications involving both analog and digital technologies, or mixed-signal systems. The mixed signal oscilloscope (MSO) [4] provides two scope channels and 16 logic channels so that it can display both the analog and digital operation of a mixed-signal system on its display.
4. **What sampling speed?** Do not simply pick the scope with the highest banner specification. One needs to ask, what is the sampling speed at the sweep speeds that my application is most likely to require? As observed in Equation 37.51 the scope's sampling speed is a function of memory depth and full-scale time base setting. If waveforms are mostly repetitive, one can save a lot of money by selecting an oscilloscope that provides equivalent time or random repetitive sampling.

5. **How much memory?** As previously discussed, memory depth and sampling speed are related. The memory depth required depends on the time span needed to measure and the time resolution required. The longer the time span to be captured and the finer the resolution required, the more

---

FIGURE 37.30 Bandwidth and narrow events. (a): a 5-ns wide pulse as displayed on a 500-MHz scope; (b): the same pulse displayed on a 60-MHz scope. The 60-MHz scope has a risetime of 5.8 ns, which is longer than the pulse width. This results in the pulse shape being incorrectly displayed and its amplitude being in error.
memory one will need. High-speed waveform memory is expensive. It takes time to process a longer memory, so the display will have more dead time in a long memory scope than a shallow memory model. All the suppliers of deep memory scopes provide a memory depth control. They provide this control so that the user can choose between a high-speed display and deep memory for the application at hand. Hewlett Packard introduced MegaZoom (TM) technology [3] in 1996; it produces a high-speed low dead-time display with deep memory all the time.

6. **Triggering?** All scope manufacturers are adding new triggering features to their products. These features are important because they allow for triggering on very specific events. This can be a valuable troubleshooting tool because it will let the user prove whether a suspected condition exists or not. Extra triggering features add complexity to the scope’s user interface; so be sure to try them out to make sure that they can be applied.

7. **Trustworthy display?** Three factors critically affect a scope’s ability to display the unknown and complex signals that are encountered in oscilloscope applications. If the user loses confidence in the scope’s ability to correctly display what is going on at its probe tip, productivity will take a real hit. These are display update rate, dead-time, and aliasing.

    Because all digital scopes operate on sampled data, they are subject to aliasing. An alias is a false reconstruction of the signal caused by under-sampling the original. An alias will always be displayed as a lower frequency than the actual signal. Some vendors employ proprietary techniques to minimize the likelihood of this problem occurring. Be sure to test any scope being considered for purchase on your worst-case signal to see if it produces a correct or aliased display. Do not simply test it with a single-shot signal that will be captured at the scope’s fastest sweep speed because this will fail to test the scope’s ability to correctly display signals that require slower sweep speeds.

8. **Analysis functions?** Digital oscilloscopes with their embedded microprocessors have the ability to perform mathematical operations that can give additional insight into waveforms. These operations often include addition, subtraction, multiplication, integration, and differentiation. An FFT can be a powerful tool, but do not be misled into thinking it is a replacement for a spectrum analyzer. Be sure to check the implementation of these features in any scope being considered. For example, does the FFT provide a selection of window functions? Are these analysis functions implemented with a control system that only their designer could apply?

9. **Computer I/O?** Most of the digital scopes on the market today can be interfaced to a PC. Most of the scope manufacturers also provide some software that simplifies the task of making the scope and PC work together. Trace images can be incorporated into documents as either PCX or TIF files. Waveform data can be transferred to spreadsheet applications for additional analysis. Some scope models are supplied with a disk drive that can store either waveform data or trace images.

10. **Try it out?** Now one has the information to narrow oscilloscope selection to a few models based on bandwidth, sampling speed, memory depth, and budget requirements. Contact the scope vendors (Table 37.3) and ask for an evaluation unit. While the evaluation unit is in the lab, look for the following characteristics:

    - Control panel responsiveness: Does the scope respond quickly to inputs or does it have to think about it for a while?
    - Control panel layout: Are the various functions clearly labeled? Does the user have to refer to the manual even for simple things?
    - Display speed: Turn on a couple of automatic measurements and check that the display speed remains fast enough to follow changing signals.
    - Aliasing: Does the scope produce an alias when the time base is reduced from fast to slow sweep speeds? How does the display look for the toughest signal?

The oscilloscope is undergoing a period of rapid change. The major manufacturers of oscilloscopes are no longer producing analog models and the digital models are evolving rapidly. There is confusion in the oscilloscope marketplace because of the rapid pace of this change. Hopefully, this discussion will prove valuable to the user in selecting and applying oscilloscopes in the lab in the years to come.

37.3 Inductive and Capacitive Voltage Measurement

Cipriano Bartoletti, Luca Podestà, and Giancarlo Sacerdoti

This chapter section addresses electrical measurements where the voltage range to be measured is very large — from $10^{-10}$ V to $10^7$ V. The waveform can be continuous, periodic, or impulsive. If it is periodic, the spectrum components can vary for different situations, and within the same electric power network there may be subharmonic components. In impulsive voltage measurement, it is often important to get maximum value, pulse length, etc. Capacitive and inductive voltage sensors are mainly utilized in low-frequency electric measurements.

Capacitive Sensors

The voltage to be measured can be reduced by means of capacitive dividers (Figure 37.31). Capacitive dividers are affected by temperature and frequency and therefore are not important, at least in Europe. Capacitive sensors detect voltage by different methods:

1. Electrostatic force (or torque)
2. Kerr or Pockels effect
3. Josephson effect
4. Transparency through a liquid crystal device
5. Change in refractive index of the optic fiber or in light pipe

1. The relations that rule the listed capacitive voltage sensors are reported below. The force between two electrodes is (Figure 37.32):

$$ F = \varepsilon_0 \frac{S}{d} (V_1 - V_2)^2 $$

(37.54)

![FIGURE 37.31 Schematic arrangement of a capacitive divider.](image)

![FIGURE 37.32 Force between two electrodes with an applied voltage.](image)
where \( \varepsilon_0 \) = Dielectric constant
\( S \) = Area of the electrode
\( d \) = Distance
\( V_1, V_2 \) = Potentials of the electrodes

The torque between electrostatic voltmeter quadrants (Figure 37.33) is given by:

\[
T = \frac{1}{2} \frac{\partial C}{\partial \theta} (V_1 - V_2)^2
\]  
(37.55)

where \( C \) = Capacitance
\( \theta \) = Angle between electrodes

To get the torque from the rate of change (derivative) of electrostatic energy vs. the angle is easy. Obtaining the torque by mapping the electric field is difficult and requires long and complex field computing.

2. The rotation of the polarization plane of a light beam passing through a KDP crystal under the influence of an electric field (Pockels effect) is expressed by (Figure 37.34):

\[
\theta = k_p l (V_1 - V_2)
\]  
(37.56)

where \( k_p \) = Electro-optic constant
\( l \) = Length of crystal

One obtains a rotation of \( \pi/2 \) by applying a voltage of the order of 1 kV to a KDP crystal of a few centimeters in length.

If a light beam passes through a light pipe that performs the Kerr effect, one observes a quadratic dependence of the rotation vs. \( V \):

\[
\theta = kE^2 \equiv k'V^2
\]  
(37.57)
3. The Josephson effect consists of translation of a voltage into a periodical signal of a certain frequency, carried out by a special capacitive sensor. There is an array of $N$ layers of Josephson superconducting junctions; the frequency of emitted signal, when a voltage $V$ is applied, is given by:

$$\nu = \frac{2eV}{Nh}$$  \hspace{1cm} (37.58)

4. The transparency of a liquid crystal device depends on the difference of potential applied. There are liquid crystal devices working in transmission or in reflection. A change in transparency is obtained when a difference of potential of a few volts is applied.

5. The change in refractive index due to the presence of an electric field can be detected by:

- Interferometric methods (where the velocity of light is equal to $c/n$)
- Change in light intensity in a beam passing through an optical wave guide device like Li-Nb (Figure 37.35).

By means of method 1, many kinds of instruments (voltmeters) can be realized. Methods 2 through 5 are used in research laboratories but are not yet used in industrial measurements.
**Inductive Sensors**

**Voltage Transformers (VTs)**

Voltage transformers have two different tasks:

- Reduction in voltage values for meeting the range of normal measuring instruments or protection relays
- Insulation of the measuring circuit from power circuits (necessary when voltage values are over 600 V)

Voltage transformers are composed of two windings — one primary and one secondary winding. The primary winding must be connected to power circuits; the secondary to measuring or protection circuits. Electrically, these two windings are insulated but are connected magnetically by the core.

One can define:

\[
\text{Nominal ratio} = K_n = \frac{V_{1n}}{V_{2n}} \tag{37.59}
\]

as the ratio between the magnitude of primary and secondary rated voltages.

\[
\text{Actual ratio} = K = \frac{V_1}{V_2} \tag{37.60}
\]

as the ratio between the magnitudes of primary and secondary actual voltages.

**Burden** is the value of the apparent power (normally at \(\cos \phi = 0.8\)) that can be provided on the secondary circuit (instruments plus connecting cables).

Burden limits the maximum value of secondary current and then the minimum value of impedance of the secondary circuit is:

\[
Z_{\text{min}} = \frac{V_{2n}^2}{A_n} \tag{37.61}
\]

where \(A_n = \text{VT burden}\)

For example, if \(A_n = 25 \text{ VA}\) and \(V_{2n} = 100 \text{ V}\), one obtains:

\[
Z_{\text{min}} = \frac{100^2}{0.25} = 400 \text{ W} \tag{37.62}
\]

There are two kinds of errors:

1. **Ratio error** = \(h_n = \frac{K_n - K}{K} \tag{37.63}\)
2. **Angle error** = the phase displacement between the primary voltage and the secondary voltage (positive if the primary voltage lags the secondary one).

Voltage transformers are subdivided into accuracy classes related to the limits in ratio and angle error (according to CEI and IEC normative classes 0.1, 0.2, 0.5, 1, 3; see Table 37.4). To choose the voltage transformer needed, the following technical data must be followed:
• Primary and secondary voltage (rated transformation ratio). Normally, the secondary value is 100 V.
• Accuracy class and rated burden in VA: e.g., cl. 0.5 and $A_n = 10$ VA.
• Rated working voltage and frequency
• Insulation voltage
• Voltage factor: the ratio between maximum operating voltage permitted and the rated voltage. The standard voltage factor is $1.2 V_n$ (i.e., the actual primary voltage) for an unlimited period of time (with VT connected with phases), and is $1.9 V_n$ for a period of 8 h for VT connected between phase and neutral.
• Thermal power is the maximum burden withstood by VT (errors excluded).

For extremely high voltage values, both capacitive dividers and voltage transformers are normally used, as shown in Figure 37.36. The capacitive impedance must compensate for the effect of the transformer’s internal inductive impedance at the working frequency.

Other Methods

The ac voltage inductive sensors act by interaction between a magnetic field (by an electromagnet excited by voltage to be measured) and the eddy current induced in an electroconductive disk, producing a force or a torque. This can be achieved by the scheme shown in Figure 37.37. The weight of many parts of the indicator can be some tens of grams. The power absorbed is on the order of a few watts. The precision is not high, but it is possible to get these sensors or instruments as they are similar to the widely produced induction energy meters. They are quite robust and are priced between $50 and $100, but they are not widely used. The relation between torque and voltage is quadratic:

$$ T = k V^2 $$  \hspace{1cm} (37.64)

The proportionality factor $k$ depends on magnet characteristics and disk geometry.

G.E.C., Landys & Gyr, A.B.B., Schlumberger, etc. are the major companies that furnish components and instruments measuring voltage by inductive and capacitive sensors.

38.20 Where to Get Current Sensors

Current measuring devices are selected for:

- Precision
- Stability
- Frequency response, including dc
- Galvanic isolation
- Presentation of the data
- Effect on measured circuit

A few of the most common sensors will be introduced in this chapter. Details and some less common sensors will follow after definitions and a bit of magnetic theory, which can be skipped. Any magnetic field sensor can be used as a current sensor and there are some exotic examples, such as quantum effects in low-temperature superconductors used to measure currents in neurons within the brain. This discussion is limited to measurement of currents in wires with commercially practical devices.

An isolated current sensor is free of any metallic connection to the circuit being measured. It is also essentially free of capacitive coupling so that it is safe to use with grounded amplifiers and other equipment. The quality of the isolation is measured in volts and is usually the breakdown potential of an insulator. 5 kV is typical for personal safety around light industrial power.
By far, the simplest current-to-voltage converter is the resistor. In current measuring service, it is called a shunt although it is typically placed in series with the load. That is because shunts are sometimes used to increase the range of another current-measuring device using a connection that bypasses part of the current around a meter. Frequency response of a shunt is good and includes dc. Shunts produce a voltage output that can be presented by a variety of secondary meters, including analog meters, digital meters, oscilloscopes, and 4- to 20-mA converters. Shunts provide no isolation and have a potentially unacceptable effect on the circuit being measured. Shunts used for dc are as accurate as the resistance and the associated voltmeter.

The common moving-coil meter, the D’Arsonval movement [1, 2], probably with an internal shunt and/or rectifier, is an easily used device and still available. Its isolation is by means of the human eye since that is the only way to read out the result. It is useful for power panels where an operator needs quick data. Accuracy is no better than 2%.

For power frequency, 25 Hz to 400 Hz service, the current transformer, called a “donut” transformer, or CT in the trade, is commonly employed. The current-carrying conductor is passed through the hole in a toroid of magnetic material. A shorted secondary winding of \( n \) turns carries current, which is \( 1/n \) times the measured current, and is typically passed to another ammeter or used as the current input to a power measuring device. Isolation is as good as the insulation on the primary conductor; frequency response is fair but does not include dc; there is minimal effect on the measured circuit, and the cost is low. Operational safety is an issue; see the note below.

A variety of noncontact sensors is available for dc sensing. Most depend on the Hall effect and all require a source of operating power. Frequency response from dc to 200 kHz is advertised. Because operating power is available, output to later processing can be voltage, current, or digital. Accuracy is whatever one wants to pay for. Long-term stability depends on dc-coupled operational amplifiers and can exhibit zero drift. Externally, these look much like CTs.

CTs, Hall devices, and other similar noncontact schemes are available in wrap-around form so they can be installed without disconnecting power. The wrapping process always involves breaking a magnetic path, and consistency of reassembly becomes a limit on precision. Everything from current-sensing probes for oscilloscopes to CTs for 10000-A circuits can be found as wrap-arounds.

### 38.1 Definition of the Ampere

There is perpetual argument about the number of “fundamental” quantities required to describe our environment. Is there a fundamental unit of electricity or are the electrical units derived from more basic things such as mass, length, and time? Standards laboratories such as the U.S. National Institute of Standards and Technology, NIST, measure the force between current carrying wires to compare the ampere to the meter, the kilogram, and the second, and provide a standard stated as “that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross-section, and placed 1 m apart in vacuum, would produce between these conductors a force equal to \( 2 \times 10^{-7} \) newton per meter of length” [3]. For the rest of this discussion, it is assumed that instrumentation is “traceable to the NIST,” meaning that one way or another, an electrical unit as measured is compared to a standard ampere maintained by NIST. Absolute calibrations using the quantum properties of the Hall effect and the Josephson junction are not practical in the field.

For practical reasons, it is often easier to distribute a voltage standard than a current standard. Chemical cells and, more recently, semiconductor voltage references are quite stable and do not depend on the length of the wires used to connect them together during calibration and use. As a result, current measuring is usually a matter of conversion of current to an equivalent voltage.

An exception is current measurement by comparison to magnetic forces provided by a permanent magnet and that might be why the older unrationlized centimeter-gram-second, the cgs units, with no separate electrical unit is still found in specifications of magnetic quantities. The gauss and the oersted are particular examples of these now deprecated units. It is this confusion of units that frightens many who would measure current away from even attempting calculations involving magnetic devices.
38.2 Magnetics

Magnetic current sensors have advantages over shunts. To understand them, one should delve into the interaction between currents and magnetic fields. Following Maxwell by way of Sommerfeld [4], it is convenient to describe magnetic effects in terms of two vector fields, \( \mathbf{B} \) and \( \mathbf{H} \). \( \mathbf{H} \) is the field created by an electric current, and \( \mathbf{B} \) is the field that acts on a moving charge or a current carrying wire. \( \mathbf{B} \) and \( \mathbf{H} \) are related by characteristics of the material in which they coexist. Strictly speaking, \( \mathbf{B} \) is the flux density and \( \mathbf{H} \) is the field, but they are both called the field in less than precise usage.

The SI units of \( \mathbf{B} \) and \( \mathbf{H} \) are the tesla (T) and the ampere per meter (A m\(^{-1}\)). They are called rationalized because a ubiquitous \( 4\pi \) has been suppressed in the underlying equations.

For practical engineering, it is still necessary to understand the unrationalized equivalents, the gauss and the oersted, because they are universally used in specifications for magnetic materials. To convert from gauss to tesla, divide by \( 10^4 \). To convert from oersted to amperes per meter, multiply by \( 1000/(4\pi) \), a number that is commonly approximated as simply 80; but strictly speaking, the units of \( \mathbf{H} \) in the two systems are dimensionally different and cannot be converted.

The relationship between \( \mathbf{B} \) and \( \mathbf{H} \) is most generally a tensor that reflects spatial anisotropy in the material, but for common magnetic materials used in current sensing, a scalar value \( \mu \) applies. In SI units, \( \mathbf{B} \) and \( \mathbf{H} \) have different physical dimensions and are not equal in vacuum. The “permeability of free space” \( \mu_0 \) is defined so that the \( \mu \) for a material is a dimensionless constant. Thus,

\[
\mathbf{B} = \mu_0 \mathbf{H}
\]

where \( \mu_0 \) is exactly \( 4\pi \times 10^{-7} \) T m\(^{-1}\). (H here is the henry, the SI unit of inductance, base units m\(^2\) kg s\(^{-2}\) A\(^{-2}\) . For many problems, \( \mu \) will be a constant of the magnetic material, but when magnetic saturation needs to be considered it will be a variable. For engineering calculations, \( \mu \) is often treated as though it depends on frequency. Values of \( \mu \) range from less than 100 for high-frequency ferrite to 5000 for transformer iron, to \( 10^5 \) for carefully annealed magnetic alloys.

The field due to a long straight wire is shown in Figure 38.1 and Equation 38.2. The \( \mathbf{H} \) vector obeys the right-hand rule and is everywhere perpendicular to the wire. The amplitude of \( \mathbf{H} \) is proportional to the current and falls off linearly with the radial distance from the wire. This is the field that makes noncontact sensing of current possible.

\[
\mathbf{H} = \frac{I}{2\pi r}
\]

The field at the center of a circular loop of wire is shown in Figure 38.2 and Equation 38.3. It obeys the right-hand rule, is proportional to the current, and inversely proportional to the radius of the loop.

\[
\mathbf{H} = \frac{I}{r}
\]

A magnetic field can often be calculated by direct application of Maxwell’s relations in integral form [4]. The line integral over any closed path of \( \mathbf{H} \cdot d\mathbf{l} \) is equal to the current passing through a surface delimited by the closed path.

Magnetic flux passing through a surface, usually denoted by \( \phi \), is the integral of \( \mathbf{B} \cdot \mathbf{n} \, dA \) over the surface with normal vector \( \mathbf{n} \). The SI unit of \( \phi \) is the weber. The unrationalized unit, the line of force, is best relegated to history except that the lines, which form continuous loops, dramatize the fact that it does not matter how a surface is drawn to close a bounding line. The flux is the same. It is convenient to think of magnetic lines, forming closed loops, that can be bent but not interrupted or removed.
A carrier of charge, an electron in a wire, a particle in vacuum, or a hole in a semiconductor, moving in a magnetic field is acted on by a force that is perpendicular to the field and the velocity. For positive charge, the force obeys the right-hand rule. The magnitude of the force is proportional to the magnitude of $B$, the velocity $V$, and the sine of the angle between them.

$$ \mathbf{F} = \mathbf{V} \times \mathbf{B} $$

(38.4)

A carrier, moving or not, is affected in a similar way by a changing magnetic field. The result is an electromotive force, $EMF$, in a loop of wire through which a changing magnetic flux passes. The $EMF$ is equal to the rate of change of the flux enclosed by the loop with a change of sign. That is Faraday's law of induction.
Most magnetic materials exhibit hysteresis. That is, the relationship between $B$ and $H$ depends on the history of the applied $H$. A plot of $B$ vs. $H$ is called a hysteresis loop and a sample is shown as Figure 38.3. The area of the loop represents an energy. If a magnetic core is repeatedly driven around its hysteresis loop, there is a power loss due to hysteresis that is proportional to the area of the loop and the frequency. A material with very large hysteresis is a permanent magnet.

Magnetic materials which are also electric conductors have free carriers which are affected by alternating magnetic fields. As they move back and forth they encounter electric resistance and dissipate energy in the form of heat. These eddy currents can be minimized by use of high resistance ferrites, powdered iron, by laminating cores, or by keeping the flux small.

### 38.3 Shunts

Shunts were introduced above. They dissipate power as heat and the resistance changes in response to the rising temperature. The dissipation is proportional to the voltage across the shunt and a design compromise must be made because low voltage implies less accuracy in the voltmeter. A standard of 50 mV has evolved. Shunts do not provide galvanic isolation between the measured circuit and the measurement device.

Measurement of alternating current using shunts is also affected by skin effect and the inductance of the shunt. Skin effect can be minimized in the design of the shunt by the use of several parallel sheets of thin metal, Figure 38.4, a feature that also improves heat dissipation. There is not much to be done about inductance except to minimize size.

Safety is enhanced if shunts are placed in the ground leg of a circuit; that way, the output leads, usually only at 50 mV, are near ground. However, that introduces a resistance in the ground path and can interfere.
with common mode requirements of interdevice signal connections. If the shunt is placed in the high side, care must be taken to protect the wiring and the meter to which it is attached from accidental grounds.

Sometimes, sufficient accuracy can be obtained by measuring the voltage drop along a length of conductor that is otherwise required in the installation. In vehicular service, it is common to sense the voltage drop in a battery cable using a millivoltmeter. Such installations are always high side and should be protected with fuses installed near the points of measurement. It is also wise to provide a connection means that is independent of contact resistance where the current-carrying conductor is installed — a Kelvin connection. Including one lead of an in-line fuse holder in the terminals before they are crimped is one such technique.

38.4 The Moving Magnet Meter

The simplest current indicator balances the force on a permanent magnet created by current in a wire against a spring. A magnetic material is usually placed around the conductor to concentrate the field and reduce the effect of the magnetic field of the Earth. Use is limited to low-precision indicators such as a battery charging meter for a vehicle. It is a dc device.

38.5 The D’Arsonval Meter

This indicator balances the force on a current-carrying wire due to a permanent magnet against a spring. The measured current flows in a coil of wire supported in bearings. It is described in elementary texts [1, 2]. It is generally a dc instrument, but chart recorders have been built with frequency response in the kilohertz range using mirrors on the moving coil. They are then called galvanometers. For ac service, these meters are often equipped with internal copper oxide rectifiers and a nonlinear scale to correct for the diode drop. For current ranges above a few milliamperes, they will have an internal shunt.

The moving magnet meter and the D’Arsonval movement are the only current sensors that do not convert current to voltage and then depend on other devices to read out the voltage.
38.6 The Electrodynamometer

A variation of the D’Arsonval meter for ac service can be built by replacing the permanent magnet with an electromagnet. The force on the moving coil becomes proportional to both the current being measured and the voltage applied to the coil of the electromagnet. It is sensitive to the relative phase of the voltage and current in just the right way to be useful for measurement of power in a circuit with correction for power factor. An electrodynamometer in a power panel is often the load for a current transformer.

38.7 The RF Ammeter and True rms

Current to a radio transmitting antenna is commonly passed through a small resistor, a shunt, that is thermally connected to a thermocouple or other thermometer and mounted in a thermally insulating blanket. The rise in temperature is a measure of the current and is often sensed with a thermocouple.

This is an example of true rms indication. Root mean square current is the square root of the integral of the square of the instantaneous current over an unspecified time divided by that time. It is intended to represent a stationary ac waveform by a single value that is equal to the direct current which would dissipate the same power in a resistive load. The RF ammeter does that precisely. The indication is not particularly linear, but it can easily be calibrated by applying dc to the input.

Other schemes for measuring rms current depend on analog multipliers and subsequent integration. They are limited by crest factor, the ratio of highest instantaneous peak to the rms over a measuring period. Inexpensive meters simply measure the peak, assume a sinusoidal waveform, and scale to rms.

38.8 The Current Transformer

Consider the magnetics of a toroidal core of high-μ material through which a current-carrying conductor passes. Include a secondary winding of \( n \) turns as shown in Figure 38.5. The secondary winding is connected to a low-resistance load.

In this current transformer, universally referred to as a CT, alternating current in the single-turn primary attempts to magnetize the core but in so doing, creates an emf and current in the secondary that tend to cancel the field. If the secondary truly has zero resistance, the current in it exactly cancels the field due to the primary. The result is a secondary current equal to the primary current divided by the number of secondary turns. The secondary current is in phase with the primary current. Because of the tightly closed magnetic loop, there is little effect from nearby conductors or position of the primary wire in the hole.

The secondary circuit can now be connected to a low-resistance current- or power-sensing device with assurance of calibration. But the secondary resistance is never really zero and the magnetic coupling is never perfect, so there are other considerations.

First, the concept of secondary burden is introduced. It is called that to avoid calling it a “load” because it behaves differently; the best burden is a short-circuit. Burden is sometimes expressed as a secondary resistance in ohms, but more often as an equivalent power in kVA for a defined current without consideration of phase. When the burden is not a perfect short-circuit, energy is dissipated and the magnetic field present in the core is no longer zero. The secondary current leads the primary current with a phase that depends on frequency.

Manufacturers of CTs have techniques to optimize accuracy of the CT when specified for a particular burden. The finished units might not have the number of secondary turns one would expect, but will nonetheless provide results accurate to a percent or so. They have laminations selected to minimize heating of the core. One will see ratings like 100:5, meaning 100 A in the primary will produce 5 A in the secondary rather than “20 turns.” They should be installed in a circuit that provides the burden for which they were calibrated. The voltage across a burden resistor is commonly amplified and passed to a data collection device. CTs for large currents need to be large to avoid magnetic saturation when burdened.
Cores are prepared with laminates of silicon iron in the form of disks, concentric rings, or tape that is wound on a bobbin. Even with the best of materials, eddy current and hysteresis loss are present. When power dissipation is unacceptable, another choice of sensor might be preferable.

Most CTs are used for measurement of low-frequency power and energy. They are found at the front end of kilowatt-hour meters used by power providers. Radio frequency current in transmitting antennas can be measured with suitable core material. Ferrite cores with appropriate compensation are used for sensing pulse width modulated current in switching power supplies. Very large cores are used to sense pulsing beams of high-energy particles. Some oscilloscope probes are highly compensated CTs with a core that can be opened to allow a current-carrying wire to be introduced. With modern winding equipment for toroids, it is possible to put 2000 or more turns on a secondary [Coilcraft]. The CT then begins to look more like a current to voltage converter in its own right without need for very small values of the burden resistor and subsequent voltage amplification.

Safety Note

The secondary of a CT should always remain shorted while there is any possibility of current flow in the primary. With an open secondary, the core can be driven back and forth between saturation in opposite directions, resulting in high-speed changes in the internal \( B \) field. The result is very high, dangerous to life, voltages on the open secondary. Insulation in the secondary circuit can be damaged by arcing. Many CTs are made with a provision for shorting the secondary if the circuit must be opened. Use it.

38.9 Gapped Inductive Sensors

It is common practice in the design of transformers to introduce a small gap in the magnetic path. For even very small gaps, the magnetic properties of the magnetic loop become almost completely determined.
by the length of the gap, the rest of the material serving only to contain the lines of flux. Analysis of such a device begins with understanding that the $B$ field is continuous in the core and through the gap. The $H$ field is not, but it still satisfies the relation that the line integral of $\mathbf{H} \cdot d\mathbf{l}$ around the core is equal to the linked current. For a magnetic path of length $s$ in material of permeability $\mu$ with a gap $g$, the ratio $B/H$, the effective permeability is given by:

$$\mu_{\text{eff}} = \frac{s}{g + \frac{s}{\mu}}$$

which applies for $g$ much smaller than $s$. Note that when $\mu$ is sufficiently large, the effective permeability becomes independent of $\mu$.

Introducing a gap into what would otherwise be a CT and drastically increasing the secondary turns count to 10000 or more results in a current sensor that is intrinsically safe because the core cannot saturate: Figure 38.6 [SRT]. Because the $B$ field is always small, the heating effect of eddy currents is less important than in the CT. When loaded with an appropriate resistor, the high inductance of the secondary causes the sensor to act like a current source that generates a voltage across the load proportional to the primary current with better than 1% linearity. Useful bandwidths of a sensor can be over 3 decades. The output impedance is high and requires the use of electronic voltmeters. Power dissipation is low, even for very high current models. Output voltage is high enough that simple diode rectifiers can be used to provide for dc output to further processing. In many cases, such a sensor can be used without any special electronics other than a voltmeter.
38.10 Hall Effect Sensor

The Hall effect as a sensor for magnetic fields is described in Chapter 48 of this volume and in [5]. It depends on a semiconductor crystal selected for its high carrier mobility and is placed in a magnetic field. A current is passed through the crystal along an axis perpendicular to the field. The carriers assume a mean velocity that causes them to be acted upon by the field and they move toward the other axis perpendicular to the field. The result is an emf at the faces of the crystal that can be measured. The emf is proportional to the field, the bias current, and the mobility.

In principle, such a field sensor could be placed near a current-carrying wire and oriented to sense the field created by the current, Figure 38.1, but the sensitivity is insufficient and there would always be interfering fields from currents in other nearby wires. A flux concentrator that looks like a CT with a large gap is always used. See Figure 38.7.

The device is sensitive to direct current and the polarity is preserved. The Hall voltage is a few millivolts and amplification is always required. Zero drift in the amplifiers must be properly compensated although this is not so important for ac service. The bias current must be carefully controlled and it can be used to provide intrinsic analog multiplication and metering of power if it is made proportional to the circuit voltage.

Sensitivity is best with the smallest gap but there must be room for the crystal so gaps are larger than in the gapped inductive sensors. Fringing of the field in the larger gap reduces the natural shielding of the toroid from unwanted magnetic fields.

The accuracy and linearity of the Hall effect sensor can be improved in closed-loop mode. A feedback winding is added to the core and driven by a servo amplifier. The emf from the Hall device is used to drive the servo amplifier until the field is zero. The output is then the feedback current which is less than the sensed current by the number of turns in the feedback winding. The frequency response of the closed-loop system is surprisingly good, hundreds of kilohertz [F.W. Bell].
38.11 Clamp-on Sensors

It is often desirable to measure current in an existing system without removing power in order to install a device; thus, most of the magnetic devices are available in a clamp-on configuration. The variety ranges from tiny oscilloscope probes to clamps for 3000-A power buses.

Accuracy is always reduced in clamp-on mode because the clamp itself constitutes a gap that is uncontrollable and subject to wear. Some manufacturers provide highly polished surfaces that slide together. Others have iron fingers that interlace as the clamp is closed. Still others do not worry about it because the instrument is intended for field use where accuracy is not so critical.

Some units have handles for one-hand operation; others require a wrench or other tool. An interesting variation is the flexible core by [Flexcorp]. Installation is by bending the core and allowing it to spring back to shape.

38.12 Magnetoresistive Sensors

Most of the features of a Hall effect sensor are available if the Hall crystal is replaced by a device whose resistance changes with magnetic field. The discovery of giant magnetoresistive devices has recently made this idea attractive. [NVE]

Such devices still exhibit rather small resistance change and are sensitive to other effects such as temperature, so it is imperative that they be used in self-compensating bridge circuits in the manner of a strain gage. They are also insensitive to the polarity of the field.

Zetex has delivered magnetoresistive current sensors using thin-film permalloy in a variety of printed circuit packages. They are constructed in the form of a bridge and require bias and a differential amplifier. Measured current up to 20 A passes through the chip via its solder pins.

38.13 The Magnetic Amplifier

The efficiency of a transformer can be adjusted by a dc or low-frequency current that moves the operating point on a hysteresis curve. Excitation, a pump, is required at a higher frequency; it is passed through the transformer and then synchronously rectified and filtered into a higher power representation of the low-frequency signal. The magnetic configuration must be designed so that the pump does not put power into the signal circuit. Figure 38.8 shows one such arrangement. The pump coils are phased in series so that the associated flux cancels in the center leg of the E-E transformer core. The output coils are also in series and phased to add. When dc is applied to the center winding, it saturates both sides and reduces the signal on the output coils. More complicated arrangements can preserve polarity in the phase of the output.

As a current measuring device the magnetic amplifier leaves much to be desired in linearity and frequency response, but it does provide isolation and is limited in sensitivity only by the number of turns placed on the center winding. The 20 mA dc off-hook current in a telephone is one such application.

38.14 Fluxgates

In its simplest form, a fluxgate magnetometer uses a driving coil to drive a high-permeability rod into saturation, first in one direction and then in the other. A second winding observes the rate of change of the $B$ field inductively. In the absence of an external magnetic field, the observed signal is symmetric; but when an external field shifts the hysteresis loop to the right or left, the symmetry is lost. An amplifier tuned and phase-locked to the second harmonic of the driving frequency can be used to determine the amplitude of the external field.

In principle, such a fluxgate could be used to sense the field in the gap of a flux concentrator as with the Hall sensor, but it is too big and the linearity would be unacceptable. It is better to think of a way
Driving a toroid this way has the undesirable effect of coupling the pump energy into the circuit being measured, but one can pump two toroids in opposite directions. Now a current to be sensed passes through both cores and biases one in one direction and one in the other relative to the pump. A pickup winding senses second harmonic, which is demodulated with a phase-locked sensor to preserve the direction of the sensed current.

Linearity is improved by adding one more winding through both toroids; it is driven by a servo amplifier that is satisfied only when the amplitude of the second harmonic is zero; the flux at the measured frequency is zero. This is now the ideal current transformer. At the frequency of the sensed current, which might be dc, there is zero average flux in the toroids and the output of the servo amplifier is a true representation of the current being measured, reduced by the turns count of the servo winding.

Unfortunately, complicated electronics and considerable power are required to accomplish all of this, but the resulting accuracy is significantly better than anything other than precision shunts. Two suppliers — GMW and Holec — provide equipment that uses similar principles. Many of the details are either patented or proprietary.

38.15 Optical Sensors

The Faraday effect is a rotation of the plane of polarization of light as it passes in a transparent medium parallel to a magnetic field. Optical fibers that do not randomize polarization are available with a small Faraday coefficient. Winding such a fiber on a form to be installed around a wire so that the light propagates parallel to the field produced by current in the wire, Figure 38.1, results in a sensor. A measurable rotation proportional to the current comes about because of the long optical path. When
the myriad problems of preparation are solved, the result is a sensor that looks externally like a current transformer but has no wires. Using a reflecting ring made of yttrium-iron-garnet with a large Faraday coefficient, NIST reports sensitivity of 220 nA [6]. Matsushita Electric Industrial Company makes sensors using thin garnet films.

Analysis of the polarization requires a polarized light source and a polarization analyzer at the other. An advantage of such a sensor is that the fiber leading to and from can be long enough to allow isolation for very high voltages.

Winding and annealing of fiber sensors without destroying the polarization-preserving properties of the fiber and temperature sensitivity of the Faraday coefficient must be addressed. Further information on these sensors can be found in [7–9]. ABB, Sweden, reports a maximum detectable current of >23 kA, a sensitivity of about 2 A, and a relative error of ±0.15% [7].

### 38.16 Fault Indicators

Latching indicators which save an indication of high pulse current which was present sometime in the past are needed for power distribution systems subject to lightning strikes. Such indicators are often a bar magnet that moves into a latched position when a current pulse occurs. Readout is visual and they can be reset and installed on live wires using high-voltage tools.

### 38.17 Other Schemes

Cantor of Ford Aerospace has described a flux reset transformer scheme for measurement of direct current [10]. An oscillator and semiconductor switch periodically drive a core into reverse saturation. When the drive current is switched off, the flux rises due to dc in the sense winding and produces a voltage on the drive winding that is sensed synchronously with the oscillator. No commercial device based on this principle is available.

The double-balanced mixer, familiar to RF engineers, is also a sensor for low-frequency current. The IF port is usually dc-coupled through diodes in a ring configuration. dc applied there will modulate an RF pump applied to one of the RF ports and recovered on the other. There are no known products that use this principle.

### 38.18 Some Generalities and Warnings

Except for very simple loads, the waveform of the current drawn by a load does not resemble the voltage waveform. Besides the well-known phase shift and power factor, current flows in harmonics and sub-harmonics of the power frequency. Bridge rectifiers with capacitor input filters draw pulses of current near the peaks of the voltage waveform. Triacs cause a phase shift of the fundamental and introduce odd harmonics. Triacs in full-cycle mode with zero current switching can draw full current for a few cycles, followed by zero current for a few more introducing frequency components below the power frequency. Frequency changers are likely to draw current in pulse width modulated bursts.

A classic error is to measure true rms voltage and true rms current and multiply the two to get power. Even after correcting for phase, this is usually wrong. In short, accurate measurement demands some knowledge of the characteristics of the load. Beware of sensors labeled “true rms” for they can be anything but.

### 38.19 Current Actuated Switches and Indicators

Another form taken by current sensors is the current actuated switch. There was a time when contacts were placed on the pointer of a D’Arsonval movement to establish upper and lower limits for a process variable. The modern way is to configure a sensor so that it operates a solid-state switch.
When operating power is available, any of the current sensors can be configured as a switch; but when the switch must be controlled solely by the power that can be extracted from the current being measured, the gapped toroid is superior. The high voltage available can be rectified to control MOSFETs or the base of an open collector Darlington transistor [SRT].

One company — CR Magnetics — markets a light-emitting diode, LED, indicator that shows the presence of alternating current without any connection or external source of power.

Circuit breakers can be implemented with a magnetic coil or with a bimetallic thermal element. For completeness, there is also the fuse.

Ground fault breakers use a toroidal CT through which the line current is passed twice: once on the way to the load and again on the way back to the neutral wire in such a way as to cancel. Any fault current to ground associated with the load causes the return current to be less than the source and induces voltage on the secondary of the toroid. This is amplified and used to trip a switch. This application demands absolute insensitivity to the position of a current-carrying wire in the hole of the toroid. Gapped sensors typically are not suitable because of magnetic leakage.

### 38.20 Where to Get Current Sensors

CTs, shunts, and some other sensors are commodity items available from a variety of manufacturers and distributors. Well-known manufacturers of switchgear — General Electric and Westinghouse — have their own CTs for use with their power meters. Test equipment manufacturers — Simpson, Tektronix, Fluke, Extech, and the like — offer hand-held current meters. Tables 38.1 and 38.2 show distributors and manufacturers of current sensing equipment. There is no way that a list such as this can be complete. It has selected itself from those companies willing to contribute to the author’s library.

TABLE 38.2 (continued)  Selected Manufacturers of Current Sensors

EIL Instruments
10946 Golden West Drive
Hunt Valley, MD 21031-1320
Tel: (410) 584-7400, Fax: (410) 584-7561
Offers a complete line of CTs and other current transducers in a variety of accuracy classes.

Extech Instruments Corporation
335 Bear Hill Road
Waltham, MA 02154-1020
Tel: (617) 890-7440, Fax: (617) 890-7864
Builds a line of hand-held meters suitable for current measurement to 2000 A.

F. W. Bell
6120 Hanging Moss Rd.
Orlando, FL 32807
Tel: (407) 677-6900, (800) 775-2550, Fax: (407) 677-5765
mbuechin@belltechinc.com
Offers noncontact sensors mostly using the Hall effect with a variety of output connections. In closed-loop mode, a 100 Adc
to 100 kHz unit can be bought for $52 plus your cost of the ±15 V to operate it.

Fluke, numerous sales offices and distributors, has a line of sensors for their hand-held instruments.

Flex-Core division of Morlan and Associates
6625 McVey Blvd.
Worthington, OH 43235
Tel: (614) 889-6152, (614) 876-8308, (614) 876-8538
Makes a line of sensors that cover the range of CTs. Of particular interest is their flexible iron core, which can be installed
over an existing conductor by bending it.

GMW Danfysik
P.O. Box 2378
Redwood City, CA 94064
Tel: (415) 802-8292, Fax: (415) 802-8298
Offers a line of laboratory grade equipment for precision noncontact measurement. Precision in the ppm range and prices
to match. Up to 10000 Adc to more than 200 kHz. Large-area CTs suitable for beam current in accelerators under the
Bergoz tradename.

Holec Power Protection B.V.
P.O. Box 4
7550 GA Hengelo
The Netherlands
Tel: +31.74.246.28.50, Fax: +31.74.246.28.00
hppbv@pi.net
Offers “zero-Flux” current transformers using servo amplifiers to drive the secondary actively. Their document 5.20.2 helps
to understand the principles involved that operate from dc to 500 kHz.

LEM U.S.
6643 West Mill Rd.
Milwaukee, WI
Tel: (414) 353-0711
Offers Hall effect sensors in both open- and closed-loop form for ac and dc currents up to 10000 A and up to 200 kHz.

Microswitch Division of Honeywell Inc.
11 W. Spring St.
Freeport, IL 61032-9945
Tel: (815) 235-6600
Offers current sensors mostly using the Hall effect, along with their line of magnetic sensors and switches.

Neilson-Kuljian
P.O. box 328
Palo Alto, CA 94302
Tel: (415) 856-3555
TABLE 38.2 (continued)  Selected Manufacturers of Current Sensors

Nonvolatile Electronics (NVE)
11409 Valley View Road
Eden Prairie, MN 55344-3617
Tel: (612) 829-9217, (800) 467-7141, Fax: (612) 996-1600
info@nve.com, http://www.nve.com
Has a giant magnetoresistive sensor in an SO8 package that could be used to make a sensor. Less than $3. Other companies are working with NVE on current sensors, but they prefer not to be known at this time.

Ohio Semitronics
4242 Reynolds Drive
Hilliard, OH
Tel: (614) 777-4611, Fax: (614) 777-4511
http://www.ohiosemi.com
Offers a wide range of current, voltage, and power transducers for ac and dc. They will soon be introducing network-capable digital output devices, including such things as harmonic analysis.

Pearson Electronics Inc.
1860 Embarcadero Road
Palo Alto, CA 94303
Tel: (415) 494-6444
Provides high-speed compensated current transformers for pulse work with oscilloscopes.

Smith Research & Technology, Inc. (SRT)
3109 S. Cascade Ave., #201
Colorado Springs, CO 80907-5190
Tel: (719) 634-2259, Fax: (719) 634-2601
http://www.srt_inc.com
Offers gapped inductive sensors with ac, dc, and 4–20-mA output up to 1000A. ac current actuated switches which control isolated 200-W loads using no external power for the switch are offered. A combined voltage and current sensor with integrated programmable microprocessor is available for harmonic analysis of power systems with network connectivity.

Sprague Electric
San Diego, CA
Tel: (619) 575-9353
Offers their model 97Z current sense transformer, which is for feedback in switching power supplies above 50 kHz.

SSAC
8220 Loop Road
Baldwinsville, NY 13027
Tel: (315) 638-1300, Fax: (305) 638-0333
Has a line of less-expensive switching products that are often found in catalogs issued by distributors.

Tektronix, numerous sales offices and distributors, has announced current sensors and hand-held instruments.

Zetex division of Telemetric PLC
Fields New Road
Chadderton, Oldham, OL9 8NP, U.K.
Tel: 0161-627-5105, Fax: 0161-627-5467
Tel: (516) 543-7100, Fax: (516) 864-7630 in the U.S.
This supplier of integrated circuits and transistors offers magnetoresistive current and magnetic field sensors for use on printed circuit boards.

Power Measurement

39.1 Power Measurements in dc Circuits

39.2 Power Measurements in ac Circuits

39.3 Pulse Power Measurements

In this chapter, the concept of electric power is first introduced, and then the most popular power measurement methods and instruments in dc, ac and pulse waveform circuits are illustrated.

Power is defined as the work performed per unit time. So, dimensionally, it is expressed as joules per second, J s\(^{-1}\). According to this general definition, electric power is the electric work or energy dissipated per unit time and, dimensionally, it yields:

\[
\text{J} \text{s}^{-1} = \text{J} \text{C}^{-1} \times \text{C} \text{s}^{-1} = \text{V} \times \text{A}
\]

(39.1)

where J = Joules
s = Seconds
C = Coulombs
V = Volts
A = Amperes

The product voltage times current gives an electrical quantity equivalent to power.

39.1 Power Measurements in dc Circuits

Electric power (P) dissipated by a load (L) fed by a dc power supply (E) is the product of the voltage across the load (V\(_{L}\)) and the current flowing in it (I\(_{L}\)):

\[
P = V_{L} \times I_{L}
\]

(39.2)

Therefore, a power measurement in a dc circuit can be generally carried out using a voltmeter (V) and an ammeter (A) according to one of the arrangements shown in Figure 39.1. In the arrangement of Figure 39.1(a), the ammeter measures the current flowing into the voltmeter, as well as that into the load; whereas in the arrangement of Figure 39.1(b), this error is avoided, but the voltmeter measures the voltage drop across the ammeter in addition to that dropping across the load. Thus, both arrangements give a surplus of power measurement absorbed by the instruments. The corresponding measurement errors are generally referred to as insertion errors.
According to the notation:

- \( I \), Current measured by the ammeter (Figure 39.1(a))
- \( V \), Voltage measured by the voltmeter (Figure 39.1(b))
- \( R_v, R_A \), Internal resistance of the voltmeter and the ammeter, respectively
- \( R_L \), Load resistance
- \( I_V \), Current flowing into the voltmeter (Figure 39.1(a))
- \( V_A \), Voltage drop across the ammeter (Figure 39.1(b))

the following expressions between the measurand electric power \( P \) and the measured power \( V \times I \) are derived by analyzing the circuits of Figures 39.1(a) and 39.1(b), respectively:

\[
P = V_I \times I_L = V \times I \times \left( \frac{R_v - R_L}{R_v} \right) \tag{39.3}
\]

\[
P = V_A \times I_L = V \times I \times \left( \frac{R_L - R_A}{R_L} \right) \tag{39.4}
\]

If:
- \( I_V \), compared with \( I \)
- \( V_A \), compared with \( V \)

are neglected for the arrangements of Figure 39.1(a) and 39.1(b), respectively, it approximately yields:

\[
\frac{I_V}{I} \equiv \frac{R_h}{R_v} \equiv \frac{R}{R_v} \equiv 0; \quad \frac{V_A}{V} \equiv \frac{R_L}{R_L + R_A} \equiv \frac{R_L}{R} \equiv 0 \tag{39.5}
\]

consequently, measured and measurand power will be coincident.

On this basis, from Equations 39.3, 39.4, and 39.5, analytical corrections of the insertion errors can be easily derived for the arrangement of Figures 39.1(a) and 39.1(b), respectively.

The instrument most commonly used for power measurement is the dynamometer. It is built by (1) two fixed coils, connected in series and positioned coaxially with space between them, and (2) a moving coil, placed between the fixed coils and equipped with a pointer (Figure 39.2(a)).

The torque produced in the dynamometer is proportional to the product of the current flowing into the fixed coils times that in the moving coil. The fixed coils, generally referred to as current coils, carry the load current while the moving coil, generally referred to as voltage coil, carries a current that is proportional, via the multiplier resistor \( R_v \), to the voltage across the load resistor \( R_L \). As a consequence, the deflection of the moving coil is proportional to the power dissipated into the load.
As for the case of Figure 39.1, insertion errors are also present in the dynamometer power measurement. In particular, by connecting the voltage coil between A and C (Figure 39.2(b)), the current coils carry the surplus current flowing into the voltage coil. Consequently, the power $P_L$ dissipated in the load can be obtained by the dynamometer reading $P$ as:

$$P_L = P - \frac{V^2}{R_v'}$$

(39.6)

where $R_v'$ is the resistance of the voltage circuit ($R_v' = R_v + R_{vc}$, where $R_{vc}$ is the resistance of the voltage coil). By connecting the moving coil between B and C, this current error can be avoided, but now the voltage coil measures the surplus voltage drop across the current coils. In this case, the corrected value is:

$$P_L = P - I^2 R_C$$

(39.7)

where $R_C$ is the resistance of the current coil.

### 39.2 Power Measurements in ac Circuits

**Definitions**

All the above considerations relate to dc power supplies. Now look at power dissipation in ac fed circuits. In this case, electric power, defined as voltage drop across the load times the current flowing through it, is the function:

$$p(t) = v(t) \times i(t)$$

(39.8)

referred to as the instantaneous power. In ac circuits, one is mainly interested in the mean value of instantaneous power for a defined time interval. In circuits fed by periodic ac voltages, it is relevant to define the mean power dissipated in one period $T$ (active power $P$):

$$P = \frac{1}{T} \int_0^T p(t) \, dt$$

(39.9)
The simplest case is a sinusoidal power supply feeding a purely resistive load. In this case, $v(t)$ and $i(t)$ are in phase and $p(t)$ is given by:

$$p(t) = VI[1 - \cos(2\omega t)]$$  \hspace{1cm} (39.10)

where $V$ and $I$ = rms values of $v(t)$ and $i(t)$, respectively

$\omega$ = power supply angular frequency

Therefore, the instantaneous power is given by a constant value $VI$ plus the ac quantity oscillating with twice the angular frequency of the power supply; thus, the active power is simply the product $VI$. In this case, all the above considerations referring to active power for dc circuits are still correct, but voltages and currents must be replaced by the corresponding rms values.

The case of purely reactive loads is the opposite; the voltage drop across the load and current flowing through it are out of phase by 90°. Instantaneous power $p(t)$ is given by:

$$p(t) = VI \cos(2\omega t)$$  \hspace{1cm} (39.11)

Thus, the active power dissipated by a reactive load is zero, owing to the phase introduced by the load itself between voltage and current.

The simplest cases of sinusoidal power sources supplying purely resistive and purely reactive loads have been discussed. In these cases, the load is expressed by a real or a pure imaginary number. In general, the load is represented by a complex quantity (the impedance value). In this case, load impedance can be represented by its equivalent circuit (e.g., a pure resistance and a pure reactance in series). With this representation in mind, the electric power dissipated in the load $Z_L$ (Figure 39.3) can be expressed by the sum of power components separately dissipated by resistance $R_{EQ}$ and reactance $X_{EQ}$ of the equivalent circuit $Z_L$.

Considering that no active power is dissipated in the reactance $X_{EQ}$, it yields:

$$P = V_{R_{EQ}}I_L = V_LI_L \cos \phi$$  \hspace{1cm} (39.12)

The term $\cos \phi$ appearing in Equation 39.12 is referred to as the power factor. It considers that only a fraction of voltage $V_L$ contributes to the power; in fact, its component $V_{XEQ}$ (the drop across the reactance) does not produce any active power, as it is orthogonal to the current $I_L$ flowing into the load.

Figure 39.4 plots the waveforms of instantaneous power $p(t)$, voltage $v(t)$, and current $i(t)$. The effect of the power factor is demonstrated by a dc component of $p(t)$ that varies from a null value (i.e., $v(t)$ and $i(t)$ displaced by 90°) toward the value $VI$ (i.e., $v(t)$ and $i(t)$ in phase).

The term:

$$P_a = V_LI_L$$  \hspace{1cm} (39.13)
is called the **apparent power**, while the term:

$$Q = V_{eq}I_L = V'_L I'_L \sin \phi$$ \hspace{1cm} (39.14)

is called the **reactive power** because it represents a quantity that is dimensionally equivalent to power. This is introduced as a consequence of the voltage drop across a pure reactance and, therefore, does not give any contribution to the active power. From Figure 39.3, the relationship existing between **apparent power**, **active power**, and **reactive power** is given by:

$$P_A = \sqrt{P^2 + Q^2}$$ \hspace{1cm} (39.15)

Dynamometers working in ac circuits are designed to integrate instantaneous power according to Equation 39.9. Insertion errors can be derived by simple considerations analogous to the dc case. However, in ac, a phase uncertainty due to the not purely resistive characteristic of voltage circuit arises. In sinusoidal conditions, if \( \varepsilon_w \) (in radians) is the phase of the real coil impedance, and \( \cos \phi \) is the load power factor, the relative uncertainty in active power measurements can be shown to be equal to \(-\varepsilon_w \tan \phi\). The phase uncertainty depends on the frequency. By using more complex circuits, the frequency range of the dynamometer can be extended to a few tens of kilohertz.

The above has presented the power definitions applied to **ac** circuits with the restrictions of sinusoidal quantities. In the most general case of distorted quantities, obviously symbolic representation can no longer be applied. In any case, active power is always defined as the mean power dissipated in one period.

As far as methods and instruments for **ac** power measurements are concerned, some circuit classification is required. In fact, the problems are different, arising in circuits as the frequency of power supply increases. Therefore, in the following, **ac** circuits will be classified into (1) line-frequency circuits, (2) low- and medium-frequency circuits (up to a few megahertz) and (3) high-frequency circuits (up to a few gigahertz). Line-frequency circuits will be discussed separately from low-frequency circuits, principally because of the existence of problems related specifically to the three-phase power supply of the main.

**Low- and Medium-Frequency Power Measurements**

In the following, the main methods and instruments for power measurements at low and medium frequencies are considered.
Three-Voltmeter Method

The power dissipation in the load $L$ can be measured using a noninductive resistor $R$ and measuring the three voltages shown in Figure 39.5 [1]. Although one of the voltages might appear redundant on a first analysis of the circuit, in actual fact, three independent data are needed in order to derive power from Equation 39.12. In particular, from voltage drops $v_{AB}$ and $v_{BC}$, the load current and load voltage can be directly derived; instead, $v_{AC}$ is used to retrieve information about their relative phase.

If currents derived by voltmeters are neglected and the current $i_L$ flowing into the load $L$ is assumed to be equal to that flowing into the resistor $R$, the statement can be demonstrated as follows:

\[
\begin{align*}
v_{AC} &= v_L + Ri_L \\
v_{AC}^2 &= R^2i_L^2 + v_L^2 + 2Rv_Li_L
\end{align*}
\]

(39.16)

where the small characters indicate instantaneous values. By computing rms values (indicated as capital characters), one obtains the power $P_L$:

\[
\begin{align*}
\frac{1}{T} \int_0^T v_{AC}^2 dt = \frac{1}{T} \int_0^T R^2i_L^2 dt + \frac{1}{T} \int_0^T v_L^2 dt + \frac{1}{T} \int_0^T 2Rv_Li_L dt \\
V_{AC}^2 &= RI_L^2 + V_L^2 + 2RP_L \\
P_L &= \frac{V_{AC}^2 - R^2I_L^2 - V_L^2}{2R} = \frac{V_{AC}^2 - V_{AB}^2 - V_{BG}^2}{2R}
\end{align*}
\]

(39.17)

Equation 39.17 is also the same in dc by replacing rms values with dc values. Since the result is obtained as a difference, problems arise from relative uncertainty when the three terms have about sum equal to zero.

Such a method is still used for high-accuracy applications.

Thermal Wattmeters

The working principle of thermal wattmeters is based on a couple of twin thermocouples whose output voltage is proportional to the square of the rms value of the currents flowing into the thermocouple heaters [2].

The principle circuit of a thermal wattmeter is shown in Figure 39.6(a). Without the load, with the hypothesis $S \ll r_1$ and $S \ll r_2$, the two heaters are connected in parallel and, if they have equal resistance $r$ ($r_1 = r_2 = r$), they are polarized by the same current $i_p$:

\[
i_1 = i_2 = \frac{i_p}{2} = \frac{v}{2R + r}
\]

(39.18)
In this case, the output voltages of the two thermo couples turn out to be equal \( e_1 = e_2 \); thus, the voltage \( \Delta e \) measured by the voltmeter is null. In Figure 39.6(b), this situation is highlighted by the working point \( T \) equal for both thermo couples. By applying a load \( L \) with a corresponding current \( i_L \), a voltage drop across \( S \) arises, causing an imbalance between currents \( i_1 \) and \( i_2 \). With the hypothesis that \( r \ll R \), the two heaters are in series; thus, the current imbalance through them is:

\[
i_1 - i_2 = \frac{S_1}{2R}
\]  \hspace{1cm} (39.19)

This imbalance increases the current \( i_1 \) and decreases \( i_2 \). Therefore, the working points of the two thermo couples change: the thermocouple polarized by the current \( i_1 \) operates at \( A \), and the other thermocouple operates at \( B \) (Figure 39.6(b)). In this situation, with the above hypotheses, the voltmeter measures the voltage imbalance \( \Delta e \) proportional to the active power absorbed by the load (except for the surplus given by the powers dissipated in \( R \), \( S \), \( r_1 \), and \( r_2 \)):

\[
\Delta e = k\left( \left< \frac{q^2}{e^2} \right> - \left< \frac{q^2}{e^2} \right> \right) = k\left( \left< \left( i_p + i_L \right)^2 \right> - \left< \left( i_p - i_L \right)^2 \right> \right)
\]

\[
= k\left< 4i_p i_L \right> = k\left< v(t)\dot{i}(t) \right> = k_i P
\]  \hspace{1cm} (39.20)

where the notation \( \left< \right> \) indicates the time average of the quantity \( i \).

If the two thermo couples cannot be considered as twins and linear, the power measurement accuracy will be obviously compromised. This situation is shown in Figure 39.7 where the two thermo couples are supposed to have two quite different nonlinear characteristics. In this case, the voltage measured by voltmeter will be \( \Delta e_0 \) instead of \( \Delta e \).

Wattmeters based on thermal principle allow high accuracy to be achieved in critical cases of highly distorted wide-band spectrum signals.

**Wattmeters Based on Multipliers**

The multiplication and averaging processes (Figure 39.8) involved in power measurements can be undertaken by electronic means.

Electronic wattmeters fall into two categories, depending on whether multiplication and averaging operations are performed in a continuous or discrete way. In continuous methods, multiplications are mainly carried out by means of analog electronic multipliers. In discrete methods, sampling wattmeters take simultaneous samples of voltage and current waveforms, digitize these values, and provide multiplication and averaging using digital techniques.
Analogous to the case of dynamometers, the resistances of the voltage and current circuits have to be taken into account (see Equations 39.6 and 39.7). Also, phase errors of both current $e_{wc}$ and voltage $e_{wv}$ circuits increase the relative uncertainty of power measurement, e.g., in case of sinusoidal conditions increased at $(e_{wc}^2+e_{wv}^2)^{0.5}$.

**Wattmeters Based on Analog Multipliers**

The main analog multipliers are based on a transistor-based popular circuit such as a four-quadrant multiplier [3], which processes voltage and current to give the instantaneous power, and an integrator to provide the mean power (Figure 39.9). More effective solutions are based on (1) Time Division Multipliers (TDMs), and (2) Hall effect-based multipliers.
TDM-Based Wattmeters.

The block diagram of a wattmeter based on a TDM is shown in Figure 39.10 [4]. A square wave $v_m$ (Figure 39.11(a)) with constant period $T_g$ and duty cycle and amplitude determined by $i(t)$ and $v(t)$, respectively, is generated. If $T_g$ is much smaller than the period of measurands $v_x(t)$ and $v_y(t)$, these voltages can be considered as constant during this time interval.

The duty cycle of $v_m$ is set by an impulse duration modulator circuit (Figure 39.10). The ramp voltage $v_y(t)$ (Figure 39.11(b)) is compared to the voltage $v_x(t)$ proportional to $i(t)$, and a time interval $t_2$, whose duration is proportional to $v_y(t)$, is determined. If
\[ v_x(t) = \frac{4V_{g0}}{T_g} t \quad \text{when} \quad 0 \leq t \leq \frac{T_g}{4} \]  

(39.21)

then from simple geometrical considerations, one obtains:

\[ t_2 = 2 \left( \frac{T_g}{4} - \frac{v_y T_g}{4V_{g0}} \right) \]  

(39.22)

and

\[ t_1 - t_2 = \frac{T_g}{V_{g0}} v_y \]  

(39.23)

The amplitude of \( v_m(t) \) is set by an impulse amplitude modulator circuit. The output square wave of the impulse duration modulator drives the output \( v_m(t) \) of the switch SW to be equal to \( +v_x \) during the time interval \( t_1 \) and to \( -v_x \) during the time interval \( t_2 \) (Figure 39.11(a)).

Then, after an initial transient, the output voltage \( v_{\text{out}}(t) \) of the low-pass filter (integrator) is the mean value of \( v_m(t) \):

\[ V_{\text{out}} = \frac{1}{RC} \int_0^T v_m(t) \, dt = K \left( \int_0^{t_1} v_x(t) \, dt - \int_{t_1}^{t_1 + t_2} v_x(t) \, dt \right) = KV_x(t_1 - t_2) = K v_x v_y \]  

(39.24)

The high-frequency limit of this wattmeter is determined by the low-pass filter and it must be smaller than half of the frequency of the signal \( v_g(t) \). The frequency limit is generally between 200 Hz and 20 kHz, and can reach 100 kHz. Uncertainties are typically 0.01 to 0.02% [5].

Hall Effect-Based Wattmeters.

As is well known, in a Hall-effect transducer, the voltage \( v_H(t) \) is proportional to the product of two time-dependent quantities [6]:

\[ v_H(t) = R_H i(t) B(t) \]  

(39.25)

where \( R_H \) = Hall constant

\( i(t) \) = Current through the transducer

\( B(t) \) = Magnetic induction

In the circuit of Figure 39.12(a), the power \( P \) is determined by measuring \( v_H(t) \) through a high-input impedance averaging voltmeter, and by considering that \( v_H(t) = ai(t) \) and \( i_B(t) = bB(t) \), where \( a \) and \( b \) are proportionality factors:

\[ P = \frac{1}{T} \int_0^T v_H(t) \cdot i_B(t) \, dt = ab \frac{1}{T} \int_0^T i(t) \cdot B(t) \, dt = ab R_H V_{HI} \]  

(39.26)

where \( T \) is the measurand period, and \( V_{HI} \) the mean value of \( v_H(t) \).

In the usual realization of the Hall multiplier (0.1% up to a few megahertz), shown in Figure 39.12(a), the magnetic induction is proportional to the load current and the optimal polarizing current \( i_B \) is set by the resistor \( R_{iv} \).

For the frequency range up to megahertz, an alternative arrangement is shown in Figure 39.12(b), in which the load current \( i_L \) flows directly into the Hall device, acting as a polarizing current, and the
A magnetic field is generated by the voltage \( v \). In this same way, the temperature influence is reduced for line-frequency applications with constant-amplitude voltages and variable load currents.

In the megahertz to gigahertz range, standard wattmeters use probes in waveguides with rectifiers.

**Wattmeters Based on Digital Multipliers**

Sampling Wattmeters.

The most important wattmeter operating on discrete samples is the sampling wattmeter (Figure 39.13). It is essentially composed of two analog-to-digital input channels, each constituted by (1) a conditioner (C), (2) a sample/hold (S/H), (3) an analog-to-digital converter (ADC), (4) a digital multiplier (MUL), and (5) summing (SUM), dividing (DIV), and displaying units (DISP). The architecture is handled by a processing unit not shown in Figure 39.13.

If samples are equally spaced, the active power is evaluated as the mean of the sequence of instantaneous power samples \( p(k) \):

\[
\bar{p} = \frac{1}{N} \sum_{k=0}^{N-1} p(k) = \frac{1}{N} \sum_{k=0}^{N-1} v(k) i(k) \tag{39.27}
\]

where \( N^* \) represents the number of samples in one period of the input signal, and \( v(k) \) and \( i(k) \) are the \( k \)th samples of voltage and current, respectively. A previous estimation of the measurand fundamental period is made to adjust the summation interval of Equation 39.27 and/or the sampling period in order to carry out a synchronous sampling [7]. The sampling period can be adjusted by using a frequency

---

© 1999 by CRC Press LLC
multiplier with PLL circuit driven by the input signal [8]. Alternatively, the contribution of the sampling error is reduced by carrying out the mean on a high number of periods of the input signal.

In the time domain, the period estimation of highly distorted signals, such as Pulse Width Modulation (PWM), is made difficult by the numerous zero crossings present in the waveform. Some types of digital filters can be used for this purpose. An efficient digital way to estimate the period is the discrete integration of the PWM signal. In this way, the period of the fundamental harmonic is estimated by detecting the sign changes of the cumulative sum function [9]:

\[ S(k) = \sum_{i=1}^{k} p_i \quad k = 1, 2, \ldots, N \quad (39.28) \]

If the summation interval is extended to an integer number of periods of the \( S(k) \) function, a “quasi-synchronous” sampling [10] is achieved through a few simple operations (cumulative summation and sign detection) and the maximum synchronization error is limited to a sampling period. Through relatively small increases in computational complexity and memory size, the residual error can be further reduced through a suitable data processing algorithm; that is, the multiple convolution in the time domain of triangular windows [9]. Hence, the power measurement can be obtained as:

\[ P_b(k) = \frac{1}{2B(N-1)} \sum_{k=0}^{2B(N-1)} w(k) p(k) \quad (39.29) \]

where \( p(k) \) is the \( k \)th sample of the instantaneous power and \( w(k) \) the \( k \)th weight corresponding to the window obtained as the convolution of \( B \) triangular windows [10].

Another way to obtain the mean power is through the consideration of the harmonic components of voltages and currents in the frequency domain using the Discrete Fourier Transform [11]. In particular, a Fast Fourier Transform algorithm is used in order to improve efficiency. Successively, a two-step research of the harmonic peaks is carried out: (1) the indexes of the frequency samples corresponding to the greatest spectral peaks provide a rough estimate of the unknown frequencies when the wide-band noise superimposed onto the signal is below threshold; (2) a more accurate estimate of harmonic frequencies is carried out to determine the fractional bin frequency (i.e., the harmonic determination under the frequency resolution); to this aim, several approaches such as zero padding, interpolation techniques, and flat-top window-based technique can be applied [12].

**Line-Frequency Power Measurements**

For line applications where the power is directly derived by the source network, the assumption of infinite power source can be reliably made, and at least one of the two quantities voltage or current can be considered as sinusoidal. In this case, the definition of the power as the product of voltage and current means that only the power at the fundamental frequency can be examined [13].

**Single-Phase Measurements**

Single-phase power measurements at line frequency are carried out by following the criteria previously mentioned. In practical applications, the case of a voltage greater than 1000 V is relevant; measurements must be carried out using voltage and current transformers inserted as in the example of Figure 39.14. The relative uncertainty is equal to:

\[ \frac{\Delta P}{P} = \left( \eta_w + \eta_a + \eta_r \right) + \left( \epsilon_w + \epsilon_a + \epsilon_r \right) \tan \phi_c \quad (39.30) \]
where $\eta_w$ and $\varepsilon_w$ are the instrumental and phase uncertainty of the wattmeter, $\eta_i$ and $\eta_c$ are the ratio uncertainties of current (CT) and voltage (VT) transformers, and $\varepsilon_i$ and $\varepsilon_c$ their phase uncertainties, respectively.

If the load current exceeds the current range of the wattmeter, a current transformer must be used, even in the case of low voltages.

**Polyphase Power Measurements**

Three-phase systems are the polyphase systems most commonly used in practical industrial applications. In the following, power measurements on three-phase systems will be derived as a particular case of polyphase systems (systems with several wires) and analyzed for increasing costs: (1) balanced and symmetrical systems, (2) three-wire systems, (3) two wattmeter-based measurements, (4) unbalanced systems, (5) three wattmeter-based measurements, and (6) medium-voltage systems.

**Measurements on Systems with Several Wires**

Consider a network with sinusoidal voltages and currents composed by $n$ wires. For the currents flowing in such wires, the following relation is established:

$$\sum_{i=1}^{n} i_i = 0 \quad (39.31)$$

The network can be thought as composed of $n - 1$ single-phase independent systems, with the common return on any one of the wires (e.g., the $s^{th}$ wire). Then, the absorbed power can be measured as the sum of the readings of $n - 1$ wattmeters, each one inserted with the current circuit on a different wire and the voltmeter circuit between such a wire and the $s^{th}$ one (Figure 39.15):

$$P = \sum_{i=1}^{n-1} \left( V_i \times I_i \right) \quad (39.32)$$

The absorbed power can be also measured by referring to a generic point O external to the network. In this case, the absorbed power will be the sum of the readings of $n$ wattmeters, each inserted with the ammeter circuit on a different wire and the voltmeter circuit connected between such a wire and the point O:

$$P = \sum_{i=1}^{n} \left( V_i \times I_i \right) \quad (39.33)$$

© 1999 by CRC Press LLC
Power Measurements on Three-Wire Systems

Active power in a three-phase power system can generally be evaluated by three wattmeters connected as shown in Figure 39.16.

For each power meter, the current lead is connected on a phase wire and the voltmeter lead is connected between the same wire and an artificial neutral point O, whose position is fixed by the voltmeter impedance of power meters or by suitable external impedances.

Under these conditions, absorbed power will be the sum of the three wattmeter indications:

\[
P = \sum_{i=1}^{3} (\hat{V}_i \times \hat{I}_i)
\]  

(39.34)

If the three-phase system is provided by four wires (three phases with a neutral wire), the neutral wire is utilized as a common wire.
Symmetrical and Balanced Systems

The supply system is symmetrical and the three-phase load is balanced; that is:

\[
\begin{align*}
V_1 &= V_2 = V_3 \\
I_1 &= I_2 = I_3
\end{align*}
\]  

(39.35)

In Figure 39.17, the three possible kinds of insertion of an instrument S (an active power or a reactive power meter) are illustrated. The first (a in Figure 39.17) was described in the last subsection; if S is a wattmeter; the overall active power is given by three times its indication, and similarly for the reactive power if S is a reactive power meter. Notice that a couple of twin resistors with the same resistance \( R \) of the voltage circuit of S are placed on the other phases to balance the load.

The other two insertions are indicated by the following convention: \( S_{ijk} \) indicates a reading performed with the current leads connected to the line “\( i \)” and the voltmeter leads connected between the phases “\( j \)” and “\( k \).” If “\( i \)” is equal to “\( j \),” one is omitted (e.g., the notation \( P_{12} \) (b in Figure 39.17)). The active power absorbed by a single phase is usually referred to as \( P_i \).

The wattmeter reading corresponding to the (c) case in Figure 39.17 is equal to the reactive power \( Q_i \) involved in phase 1, save for the factor \( \sqrt{3} \). Hence, in the case of symmetrical and balanced systems, the overall reactive power is given by:

\[
Q = 3Q_i = 3P_{\{1\}(23)} \sqrt{3} = \sqrt{3} P_{\{1\}(23)}
\]  

(39.36)

In fact, one has:

\[
P_{\{1\}(23)} = I_1 \times \hat{V}_{23}
\]  

(39.37)

but:

\[
\hat{V}_{12} + \hat{V}_{23} + \hat{V}_{31} = 0 \quad \Rightarrow \quad P_{\{1\}(23)} = I_1 \times (-\hat{V}_{12} - \hat{V}_{31})
\]

\[
\hat{V}_{13} = -\hat{V}_{31} \quad \Rightarrow \quad P_{\{1\}(23)} = -I_1 \times \hat{V}_{12} + I_1 \times \hat{V}_{13}
\]

\[
\begin{align*}
I_1 \times \hat{V}_{12} &= P_{12} \\
I_1 \times \hat{V}_{13} &= P_{13}
\end{align*}
\]

\[
\Rightarrow \quad P_{\{1\}(23)} = P_{13} - P_{12}
\]

© 1999 by CRC Press LLC
In the same manner, the following relationships, which are valid for any kind of supply and load, can be all proved:

\[ P_{(23)} = P_{13} - P_{12} \]
\[ P_{(31)} = P_{21} - P_{23} \]
\[ P_{(12)} = P_{32} - P_{31} \]  \hspace{1cm} (39.38)

If the supply system is symmetrical, \( P_{(23)} = \sqrt{3}Q_1 \).

In fact, moving from the relationship (Figure 39.18):

\[ P_{(23)} = I_1 \times \dot{V}_{23} = I_1 V_{23} \cos \beta \]  \hspace{1cm} (39.39)

where \( \beta = 90^\circ - \varphi_1 \), one obtains \( P_{(23)} = \sqrt{3}E_1I_1 \sin \varphi_1 = \sqrt{3}Q_1 \).

In the same manner, the other two corresponding relationships for \( P_{(31)} \) and \( P_{(12)} \) are derived. Hence:

\[ P_{(23)} = \sqrt{3}Q_1 = P_{13} - P_{12} \]
\[ P_{(31)} = \sqrt{3}Q_2 = P_{21} - P_{23} \]
\[ P_{(12)} = \sqrt{3}Q_3 = P_{32} - P_{31} \]  \hspace{1cm} (39.40)

**Power Measurements Using Two Wattmeters**

The overall active power absorbed by a three-wire system can be measured using only two wattmeters. In fact, Aron’s theorem states the following relationships:

\[ P = P_{12} + P_{13} \]
\[ P = P_{23} + P_{13} \]
\[ P = P_{31} + P_{21} \]  \hspace{1cm} (39.41)
Analogously, the overall reactive power can be measured by using only two reactive power meters:

\[
Q = Q_{12} + Q_{32} \\
Q = Q_{23} + Q_{31} \\
Q = Q_{31} + Q_{32}
\]

Here one of the previous statements, that is:

\[P = P_{12} + P_{32}\]

is proved. The two wattmeters connected as shown in Figure 39.19 furnish \(P_{12}, P_{32}\):

Hence, the sum of the two readings gives:

\[
P_{12} + P_{32} = I_1 \times V_{12} + I_3 \times V_{32} = I_1 \times (\dot{E}_{1} - \dot{E}_{2}) + I_3 \times (\dot{E}_{3} - \dot{E}_{2}) \\
= I_1 \times \dot{E}_{1} - I_1 \times \dot{E}_{2} + I_3 \times \dot{E}_{3} - I_3 \times \dot{E}_{2} = I_1 \times \dot{E}_{1} + I_3 \times \dot{E}_{3} - (I_1 + I_3) \times \dot{E}_{2} \quad (39.43)
\]

\[
P_{12} + P_{32} = I_1 \times \dot{I}_{1} + I_3 \times \dot{I}_{3} + I_2 \times \dot{E}_{2} = P_1 + P_2 + P_3 = P
\]

Provided that the system has only three wires, Aron’s theorem applies to any kind of supply and load. In the case of symmetrical and balanced systems, it also allows the reactive power to be evaluated:

\[
Q = \sqrt{3} \cdot \left( P_{32} - P_{12} \right) \quad (39.44)
\]

Using Equations 39.41 and 39.44, the power factor is:

\[
\cos \phi = \frac{P_{12} + P_{32}}{\sqrt{(P_{12} + P_{32})^2 + 3(P_{32} - P_{12})^2}} = \frac{P_{12} + P_{32}}{\sqrt{4P_{12}^2 + 4P_{32}^2 - 4P_{12}P_{32}}} = \frac{1 + \frac{P_{12}}{P_{32}}}{\sqrt{2 \left( \frac{P_{12}}{P_{32}} \right)^2 - \left( \frac{P_{12}}{P_{32}} \right) + 1}} \quad (39.45)
\]
Aron's insertion cannot be utilized when the power factor is low. In fact, if the functions:

$$\cos(\varphi + 30) = \frac{P_1}{VI}$$

$$\cos(\varphi - 30) = \frac{P_3}{VI}$$

are considered (Figure 39.20), it can be argued that: (1) for $\varphi \leq 60^\circ$, $P_{12}$ and $P_{32}$ are both greater than zero; (2) for $\varphi > 60^\circ$, $\cos(\varphi - 30)$ is still greater than zero, and $\cos(\varphi + 30)$ is lower than zero.

The absolute error in the active power is:

$$\Delta P = \frac{\partial (P_{12} + P_{32})}{\partial P_{12}} \Delta P_{12} + \frac{\partial (P_{12} + P_{32})}{\partial P_{32}} \Delta P_{32} = \Delta P_{12} + \Delta P_{32}$$

(39.47)

This corresponding relative error is greater as $P_{12}$ and $P_{32}$ have values closer to each other and are opposite in polarity; in particular, for $\cos \varphi = 0$ ($\varphi = 90^\circ$), the error is infinite.

If $\eta_w$ and $\epsilon_w$ are the wattmeter amplitude and phase errors, respectively, then the error in the active power is:

$$\frac{\Delta P}{P} = \left( \eta_w + \epsilon_w - \frac{\partial (P_{12} + P_{32})}{\partial P_{12}} \right) \frac{P_{12}}{P_{12} + P_{32}} + \left( \eta_w + \epsilon_w - \frac{\partial (P_{12} + P_{32})}{\partial P_{32}} \right) \frac{P_{32}}{P_{12} + P_{32}} = \eta_w + \epsilon_w - \frac{Q}{P}$$

(39.48)

Let two wattmeters with nominal values $V_0$, $I_0\cos \varphi_0$ and class c be considered; the maximum absolute error in each reading is:

$$\Delta P = \frac{cV_0I_0\cos \varphi_0}{100}$$

(39.49)

Therefore, the percentage error related to the sum of the two indications is:

$$\frac{\Delta P}{P} = \frac{cV_0I_0\cos \varphi_0}{\sqrt{3}VI\cos \varphi} = 1.11 \frac{cV_0I_0\cos \varphi_0}{VI\cos \varphi}$$

(39.50)
equal to approximately the error of only one wattmeter inserted in a single-phase circuit with the same
values of $I$, $V$, and $\cos \phi$. Consequently, under the same conditions, the use of two wattmeters involves a
measurement uncertainty much lower than that using three wattmeters.

If the Aron insertion is performed via current and voltage transformers, characterized by ratio errors $\eta_a$ and $\eta_v$, and phase errors $\varepsilon_a$ and $\varepsilon_v$, respectively, the active power error is:

$$\Delta P = \left( \eta_{TOT} + \varepsilon_{TOT} \right) P + \left( \eta_{TOT} + \varepsilon_{TOT} \right) P = \eta_{TOT} + \varepsilon_{TOT} \cdot \eta_{TOT} + \varepsilon_{TOT} \cdot \eta_{TOT}$$

(39.51)

where $\cos \Phi_c = \text{Conventional power factor}

$$\eta_{TOT} = \eta_a + \eta_v + \eta_v$$

and $\varepsilon_{TOT} = \varepsilon_a + \varepsilon_v + \varepsilon_v$

the error sums with $\eta_a$ and $\varepsilon_a$ being the wattmeter errors.

Symmetrical Power Systems Supplying Unbalanced Loads

If the load is unbalanced, the current amplitudes are different from each other and their relative phase
is not equal to 120°. Two wattmeters and one voltmeter have to be connected as proposed by Barbagelata
[13] (Figure 39.21). The first wattmeter can provide $P_{12}$ and $P_{13}$, and the second one gives $P_{31}$ and $P_{32}$.

From the Aron theorem, the active power is:

$$P = P_{12} + P_{32}$$

(39.52)

and then the reactive power $Q$ is:

$$Q = Q_1 + Q_2 + Q_3 = \frac{1}{\sqrt{3}} \left[ P_{13} - P_{12} + P_{21} - P_{23} + P_{32} - P_{31} \right]$$

(39.53)

For the underlined terms, from Aron’s theorem it follows that:

$$P = P_{13} + P_{23} = P_{12} + P_{32} = P_{21} + P_{31}$$

(39.54)

then:

$$P_{13} + P_{23} = P_{12} + P_{32} \Rightarrow P_{21} - P_{23} = P_{13} - P_{31}$$
Thus, one obtains:

\[
Q = \frac{1}{\sqrt{3}} \left[ 2(P_{31} - P_{32}) + P_{21} - P_{12} \right] \tag{39.55}
\]

Therefore, using only four power measurements, the overall active and reactive powers can be obtained. The main disadvantage of this method is that the four measurements are not simultaneous; therefore, any load variations during the measurement would cause a loss in accuracy. In this case, a variation proposed by Righi [13] can be used. In this variation, three wattmeters are connected as shown in Figure 39.22 and give simultaneously \(P_{12}, P_{32},\) and \(P_{2(31)}\). Reactive power is:

\[
Q = \frac{1}{\sqrt{3}} \left[ P_{22} - P_{12} + P_{21} - P_{23} + P_{32} - P_{21} \right] \tag{39.56}
\]

Analogously as above, from the Aron theorem it follows that:

\[
P_{21} - P_{23} = P_{13} - P_{31} \Rightarrow P_{2(31)} = P_{21} - P_{23} = P_{13} - P_{31} \tag{39.57}
\]

then:

\[
Q = \frac{1}{\sqrt{3}} \left[ P_{32} - P_{12} + 2P_{2(31)} \right] \tag{39.58}
\]

For symmetrical and unbalanced systems, another two-wattmeter insertion can be carried out (Figure 39.23). The wattmeters give:

\[
P_{1[20]} = \bar{E}_1 \times \bar{I}_1 = j\frac{V_2}{\sqrt{3}} \times \bar{I}_1 = -\frac{Q_{32}}{\sqrt{3}} \tag{39.59}
\]

\[
P_{3[10]} = \bar{E}_1 \times \bar{I}_3 = j\frac{V_3}{\sqrt{3}} \times \bar{I}_3 = -\frac{Q_{32}}{\sqrt{3}}
\]

Hence, the overall reactive power is:

\[
Q = Q_{12} + Q_{32} = \sqrt{3} \left[ -P_{1[20]} + P_{3[10]} \right] \tag{39.60}
\]
Three-Wattmeter Insertion

A three-wire, three-phase system can be measured by three wattmeters connected as in Figure 39.24. The artificial neutral point position does not affect the measurement; it is usually imposed by the impedance of the voltmeter leads of the wattmeters.

Medium-Voltage, Three-Wattmeter Insertion

Analogously to the single-phase case, for medium-voltage circuits, the three-wattmeter insertion is modified as in Figure 39.25.

Method Selection Guide

For three-wire systems, the flow chart of Figure 39.26 leads to selecting the most suitable method according to system characteristics.

High-Frequency Power Measurements

Meters used for power measurements at radio or microwave frequencies are generally classified as absorption type (containing inside their own load, generally 50 Ω for RF work) and transmitted or through-line type (where the load is remote from the meter). Apart from the type, power meters are mainly based on thermistors, thermocouples, diodes, or radiation sensors. Therefore, to work properly, the sensor should sense all the RF power \( P_{\text{LOAD}} \) incoming into the sensor itself. Nevertheless, line-to-sensor impedance mismatches cause partial reflections of the incoming power \( P_{\text{INCIDENT}} \) so that a meter connected to a sensor does not account for the total amount of reflected power \( P_{\text{REFLECTED}} \). The relationship existing among power dissipated on the load, power incident, and power reflected is obviously:

\[
P_{\text{LOAD}} = P_{\text{INCIDENT}} - P_{\text{REFLECTED}}
\]  

\( (39.61) \)
Directional couplers are instruments generally used for separating incident and reflected signals so that power meters can measure each of them separately. In Figure 39.27, the longitudinal section of a directional coupler for waveguides is sketched. It is made up by two waveguides properly coupled through two holes. The upper guide is the primary waveguide and connects the power source and load; the lower guide is the secondary waveguide and is connected to the power meter. To explain the working of directional couplers, incident and reflected waves have been sketched separately in Figure 39.27(a) and 39.27(b). In particular, section a depicts a directional coupler working as incident wave separator, whereas section b shows the separation of the reflected wave. The correct working is based on the assumption that the distance between the holes matches exactly one quarter of the wave length ($\lambda$). In fact, in the secondary waveguide, each hole will give rise to two waves going in opposite directions (one outside and the other inside the waveguide); consequently, in front of each hole, two waves are summed with their own phases. The assumption made on the distance between the holes guarantees that, in front of one hole, (1) the two waves propagating outside the waveguide will be in phase, causing an enforcing effect in that direction; (2) while, in front of the other hole, the two waves (always propagating outside) will be in opposition, causing a canceling effect in that direction. The enforcing and canceling effects for incident and reflected waves are opposite. In particular, according to the directions chosen in Figure 39.27, incident power propagates on the right side and is canceled on the left side (Figure 39.27(a)), while reflected power propagates on the left side and is canceled on the right side (Figure 39.27(b)). Therefore, directional couplers allow separate measurement of incident and reflected power by means of power meters applied, respectively, on the right and on the left side of the secondary waveguide.

In any case, the secondary waveguide must be correctly matched from the impedance point of view at both sides (by adaptive loads and/or a proper choice of the power meter internal resistance) in order to avoid unwanted reflections inside the secondary waveguide.

Directional couplers are also used to determine the reflection coefficient $\rho$ of the sensor, which takes into account mismatch losses and is defined as:

$$P_{\text{REFLECTED}} = \rho^2 \times P_{\text{INCIDENT}}$$  \hspace{1cm} (39.62)

In order to take into account also the absorptive losses due to dissipation in the conducting walls of the sensor, leakage into instrumentation, power radiated into space, etc., besides the reflection coefficient, the effective efficiency $\eta_c$ of the sensor should also be considered. Generally, the reflection coefficient and effective efficiency are included into the calibration factor $K$, defined as:

$$K = \eta_c (1 - \rho^2) \times 100$$  \hspace{1cm} (39.63)
FIGURE 39.26  Method selection guide for power measurements on three-wire systems.
For example, a calibration factor of 90% means that the meter will read 10% below the incident power. Generally, calibration factors are specified by sensor manufacturers at different values of frequency.

**Thermal Methods**

In this section, the main methods based on power dissipation will be examined, namely: (1) thermistor-based, (2) thermocouple-based, and (3) calorimetric.

**Thermistor-Based Power Meters**

A thermistor is a resistor made up of a compound of highly temperature-sensitive metallic oxides [14]. If it is used as a sensor in a power meter, its resistance becomes a function of the temperature rise produced by the applied power. In Figure 39.28, typical power-resistance characteristics are reported for several values of the operating temperature.
The working principle of the thermistor power meter is illustrated in Figure 39.29 [15]: two thermistors \( R_{T1} \) and \( R_{T2} \) are connected (1) in parallel, for measurand signals appearing at the RF input \( P_{RF} \); and (2) in series, for the following measuring circuit (e.g., a bridge). The capacitance \( C_1 \) prevents the power dc component from flowing to the thermistors; the \( C_2 \) stops the RF power toward the bridge.

A bridge with a thermistor or a barretter in one arm is called a bolometer. Bolometer-based measurements can be performed with (1) a manual bolometer with variation of the bias current, (2) a manual bolometer with substitution method, or (3) a self-balancing bolometer.

The manual bolometer with \textit{a variation of the bias current} is illustrated in Figure 39.30. Its working principle consists of two steps. In the first, no RF power is applied to the sensor; the equilibrium is obtained by varying the dc power supply \( E \) until the sensor resistance \( R_B \), related to the dc power flowing in it, is equal to \( R \). In this condition, let the current \( I \) flowing into the sensor be equal to \( I_1 \). In the second step, an RF power \( P_{RF} \) is fed to the sensor; the power increase must be compensated by a dc power decrease, which is performed by lowering the bridge dc supply voltage \( E_2 \); in this case, let \( I \) be equal to \( I_2 \).

Since the power dissipated in the sensor has been maintained constant in both steps, the power \( P_{RF} \) can be evaluated as:

\[
P_{RF} = \frac{R}{4} \left( I_1^2 - I_2^2 \right) \tag{39.64}
\]

The \textit{manual bolometer with substitution method} (Figure 39.31) consists of two sequential steps; in the first, both RF power \( P_{RF} \) and dc power \( P_{dc} \) are present, and the power \( P_{d} \) necessary to lead the bridge to the equilibrium is:
During the second step, $P_{RF}$ is set to zero and an alternative voltage $V_{ac}$ is introduced in parallel to the dc power supply. In this case, the power $P_d$ necessary to balance the bridge:

$$P_d = P_{dc} + P_{RF}$$  \hspace{1cm} (39.65)

is obtained by varying $V_{ac}$. Since $P_d$ is the same in both cases, the power supplied by the alternative generator is equal to $P_{RF}$:

$$P_{RF} = P_{ac} = \frac{V_{ac}^2}{4R}$$  \hspace{1cm} (39.67)

Equation 39.66 implies that the RF power can be obtained by a voltage measurement. The self-balancing bolometer (Figure 39.32) automatically supplies a dc voltage $V$ to balance the voltage variations due to sensor resistance $R_B$ changes for an incident power $P_{RF}$. At equilibrium, $R_B$ is equal to $R$ and the RF power will then be:

$$P_{RF} = \frac{V^2}{4R}$$  \hspace{1cm} (39.68)
As mentioned above, the thermistor resistance depends on the surrounding temperature. This effect is compensated in an instrument based on two self-balancing bridges [15]. The RF power is input only to one of these, as shown in Figure 39.33.

The equilibrium voltages $V_c$ and $V_{RF}$ feed a chopping and summing circuit, whose output $V_c + V_{RF}$ goes to a voltage-to-time converter. This produces a pulse train $V_1$, whose width is proportional to $V_c + V_{RF}$. The chopping section also generates a signal with an amplitude proportional to $V_c - V_{RF}$, and a frequency of a few kilohertz, which is further amplified. The signals $V_1$ and $V_2$ enter an electronic switch whose output is measured by a medium value meter $M$. This measure is proportional to the RF power because:

$$P_{RF} = \frac{V_c + V_{RF}}{4R} \left( V_c - V_{RF} \right) \Rightarrow P_{RF} = \frac{V_c^2 - V_{RF}^2}{4R} \quad (39.69)$$

Owing to the differential structure of the two bolometers, this device is capable of performing RF power measurements independent of the surrounding temperature. In addition, an offset calibration can be carried out when $P_{RF}$ is null and $V_c$ is equal to $V_{RF}$.

These instruments can range from 10 mW to 1 µW and utilize sensors with frequency bandwidths ranging from 10 kHz to 100 GHz.

**Thermocouple-Based Power Meters**

Thermocouples [14] can be also used as RF power meters up to frequencies greater than 40 GHz. In this case, the resistor is generally a thin-film type. The sensitivity of a thermocouple can be expressed as the ratio between the dc output amplitude and the input RF power. Typical values are $160 \mu V \ mW^{-1}$ for minimum power of about 1 µW.

The measure of voltages of about some tens of millivolts requires strong amplification, in that the amplifier does not have to introduce any offset. With this aim, a chopper microvoltmeter is utilized [16], as shown in the Figure 39.34.

The thermocouple output voltage $V_{dc}$ is chopped at a frequency of about 100 Hz; the resulting square wave is filtered of its mean value by the capacitor $C$ and then input to an ac amplifier to further reduce offset problems. A detector, synchronized to the chopper, and a low-pass filter transform the amplified square voltage in a dc voltage finally measured by a voltmeter.
For high frequencies, a substitution technique based on a calorimetric method is utilized (Figure 39.35) [17]. First, the unknown radio frequency power $P_{RF}$ is sent to the measuring device $t$, which measures the equilibrium temperature. Then, once the calorimetric fluid has been cooled to its initial temperature, a dc power $P_{dc}$ is applied to the device and regulated until the same temperature increase occurs in the same time interval. In this way, a thermal energy equivalence is established between the known $P_{dc}$ and the measurand $P_{RF}$.

A comparison version of the calorimetric method is also used for lower frequency power measurements (Figure 39.36). The temperature difference $\Delta T$ of a cooling fluid between the input (1) and the output (2) sections of a cooling element where the dissipated power to be measured $P$ is determined. In this case, the power loss will correspond to $P$:

$$P = C_p \rho Q \Delta T$$  \hspace{1cm} (39.70)

where $C_p$ is the specific heat, $\rho$ the density, and $Q$ the volume flow, respectively, of the refreshing fluid.
Diode Sensor-Based Power Measurements

Very sensitive (up to 0.10 nW, –70 dBm), high-frequency (10 MHz to 20 GHz) power measurements are carried out through a diode sensor by means of the circuit in Figure 39.37 [18]. In particular, according to a suitable selection of the components in this circuit, (1) true-average power measurements, or (2) peak power measurements can be performed.

The basic concept underlying true-average power measurements exploits the nonlinear squared region of the characteristic of a low-barrier Schottky diode (non-dashed area in Figure 39.38). In this region, the current flowing through the diode is proportional to the square of the applied voltage; thus, the diode acts as a squared-characteristic sensor.

In the circuit of diode sensor-based wattmeters shown in Figure 39.37, the measurand $v_x$ terminated on the matching resistor $R_m$, is applied to the diode sensor $D_s$ working in its squared region in order to produce a corresponding output current $i_c$ in the bypass capacitor $C_b$. If $C_b$ has been suitably selected, the voltage $v_c$ between its terminals, measured by the voltmeter amplifier $V_a$, is proportional to the average of $i_c$, i.e., to the average of the squares of instantaneous values of the input signal $v_x$ and, hence, to the true average power.

In the true-average power measurement of nonsinusoidal waveforms having the biggest components at low frequency, such as radio-frequency AM (Amplitude Modulated), the value of $C_b$ must also satisfy another condition. The voltage $v_d$ on the diode must be capable of holding the diode switched-on into conduction even for the smallest values of the signal. Otherwise, in the valleys of the modulation cycle, the high-frequency modulating source is disconnected by the back-biased diode and the measurement is therefore misleading.

On the other hand, for the same signal but for a different selection of the $C_b$ value, the circuit can act as a peak detector for peak power measurements. As a matter of fact, the voltage $v_c$ on the bypass capacitor $C_b$ during the peak of the modulation cycle is so large that in the valleys, the high-frequency peaks are
not capable of switching on the diode into conduction; thus, these peaks do not contribute to the measured power level.

If higher power levels have to be measured (10 mW to 100 mW), the sensing diode is led to work out of the square region into its linear region (dashed area in Figure 39.38). In this case, the advantage of true-average power measurements for distorted waveforms is lost; and for peak power measurements, since the diode input-output characteristic is nonlinear and the output is squared, spectral components different from the fundamental introduce significant measuring errors.

**Radiation Sensor-Based Power Measurements**

Very high-frequency power measurements are usually carried out by measuring a radiant flux of an electromagnetic radiation through a suitable sensor. In particular, semiconductor-based radiation microsensors have gained wider and wider diffusion [19], in that size reduction involves several well-known advantages such as greater portability, fewer materials, a wider range of applications, etc. One of the most familiar applications of radiation sensor-based power measurements is the detection of object displacement. Furthermore, they are also commonly used for low-frequency power noninvasive measurements.

Radiation sensors can be classified according to the measurand class to which they are sensitive: nuclear particles or electromagnetic radiations. In any case, particular sensors capable of detecting both nuclear particles and electromagnetic radiations, such as gamma and X-rays, exist and are referred to as nucleonic detectors.

In Table 39.1, the different types of radiation sensors utilized according to the decrease of the measurand wavelength from microwaves up to nuclear (X, gamma, and cosmic) rays are indicated.

In particular, microwave power radiation sensors are mainly used as noncontacting detectors relying on ranging techniques using microwaves [20]. Shorter and longer (radar) wavelength microwave devices are employed to detect metric and over-kilometer displacements, respectively.

Beyond applications analogous to microwave, power radiation infrared sensors also find use as contact detectors. In particular, there are two types of infrared detectors: thermal and quantum. The thermal type includes contacting temperature sensors such as thermocouples and thermopiles, as well as noncontacting pyroelectric detectors. On the other hand, the quantum type, although characterized by a strong wavelength dependence, has a faster response and includes photoconductive (spectral range: 1 μm to 12 μm) and photovoltaic (0.5 μm to 5.5 μm) devices.

The main power radiation visible and ultraviolet sensors are photoconductive cells, photodiodes, and phototransistors. Photodiodes are widely used to detect the presence, the intensity, and the wavelength of light or ultraviolet radiations. Compared to photoconductive cells, they are more sensitive, smaller, more stable and linear, and have lower response times. On the other hand, phototransistors are more sensitive to light.

At very low light levels, rather than silicon-based microsensors, nuclear radiation power microsensors are needed. In this case, the most widespread devices are scintillation counters, solid-state detectors, plastic films, and thermoluminescent devices. The scintillation counter consists of an active material that converts the incident radiation to pulses of light, and a light-electric pulse converter. The active material can be a crystal, a plastic fluorine, or a liquid. The scintillator size varies greatly according to the radiation energy, from thin solid films to large tanks of liquid to detect cosmic rays. A thin (5 μm) plastic

polycarbonate film or a thermoluminescent material (e.g., LiF) can measure the radiation power falling on a surface. The film is mechanically damaged by the propagation of highly α-ionizing particles. Consequent etching of the film reveals tracks that can be observed and counted.

39.3 Pulse Power Measurements

Pulse waveforms are becoming more and more diffused in several fields such as telecommunications, power source applications, etc. The pulse power $P_p$ is defined as the average power $P_m$ in the pulse width:

$$P_p = \frac{P_m}{\tau_d}$$  \hspace{1cm} (39.71)

where $\tau_d$ is the duty cycle of the pulse waveform (i.e., the pulse width divided by the waveform period). If the pulse width cannot be accurately defined (e.g., nonrectangular pulses in the presence of noise), the pulse power $P_p$ becomes unmeaningful. In this case, the peak envelope power is introduced as the maximum of the instantaneous power detected on a time interval, including several periods of the pulse waveform (but negligible with respect to the modulation period, in the case of PWM waveforms).

Several techniques are used to measure pulse power [21]. In particular, they can be classified according to the pulse frequency and the necessity for constraining real-time applications (i.e., measuring times, including a few of the modulation periods). For real-time, low-frequency applications (up to 100 kHz), the algorithms mentioned in the above sections on wattmeters based on digital multipliers can be applied [9].

If constraining limits of real-time do not have to be satisfied, either digital or analog techniques can be utilized. As far as the digital techniques are concerned, for high-frequency applications, if the measurand pulse waveform is stationary over several modulation periods, digital wattmeters based on equivalent sampling can be applied, with accuracies increasing according to measuring times. As far as the analog techniques are concerned, three traditional methods are still valid: (1) average power per duty cycle, (2) integration-differentiation, and (3) dc/pulse power comparison.

A block diagram of an instrument measuring average power per duty cycle is illustrated in Figure 39.39. At first, the mean power of the measurand pulse signal, terminated on a suitable load, is measured by means of an average power meter; then, the pulse width and the pulse waveform period are measured by a digital counter. Finally, the power is obtained by means of Equation 39.71.

The integration-differentiation technique is based on a barretter sensor capable of integrating the measurand, and on a conditioning and differentiating circuit to obtain a voltage signal proportional to the measurand power. The signal is input to the barretter sensor, having a thermal constant such that the barretter resistance will correspond to the integral of the input. The barretter is mounted as an arm of a conditioning Wheatstone bridge; in this way, the barretter resistance variations are transformed into voltage variations, and an integrated voltage signal is obtained as an output of the bridge detecting arm.

\[FIGURE 39.39 \] Block diagram of an instrument measuring average power per duty cycle.
This signal, suitably integrated to reach a voltage signal proportional to the output, is detected by a peak voltmeter calibrated in power. Analogously to the selection of the time constant of an RC integrating circuit, attention must be paid to the thermal constant selection of the barretter in order to attain the desired accuracy in the integration. With respect to the measurand pulse period, a very long thermal constant will give rise to insufficient sensitivity. On the other hand, a very short constant approaching the pulse duration will give rise to insufficient accuracy.

The *dc/pulse power comparison* technique is based on the concept of first revealing the peak envelope power through a diode sensor, and then comparing the peak to a known dc source with a dual trace scope. A block diagram of an instrument based on this concept is illustrated in Figure 39.40. The peak of the measurand pulse signal terminated on a suitable load is sensed by a peak detector by obtaining a proportional signal \( V_p \). This signal is input to a channel of a dual trace oscilloscope and the envelope peak is displayed. An adjustable dc source is input to the other channel of the scope to obtain a signal \( V_{dc} \) to be compared to the envelope peak signal. When the two signals are made equal, a dc voltage meter directly calibrated in peak power measures the output power.

40.5 Instrumentation

Electricity can be thought of as a means of delivering power from one place to another to do work. The laws and relationships for delivering power were originally developed for direct current. Power delivered, expressed in watts, was calculated by multiplying the voltage and current as shown in Equation 40.1

\[ P_{dc} = EI \quad (40.1) \]

The situation becomes more complex when alternating current is used to deliver power. Figure 40.1 shows a sine wave representing either ac current or voltage. Since the instantaneous value of the wave is continually changing, a numerical quantity is defined to represent an average property of this wave. This quantity, the root-mean-square, or rms value, calculated by squaring the instantaneous value, integrating it during one cycle, dividing by the period, and taking the square root of the result, is equal to the peak value of the ac wave divided by the square root of 2, or, for ac current, \( I_{\text{rms}} = \frac{i_{\text{peak}}}{\sqrt{2}} \). In the physical world, a sine wave ac current having an rms value of 1 A (A = ampere), passed through a resistive load, produces the same heating effect as 1 A of dc current. Thus, one might expect delivered ac power to be easily calculated in watts using Equation 40.1 and inserting rms values for current and voltage. While this simple relationship holds true for the instantaneous voltage and current values as shown in Equation 40.1a in general, it is not true for the rms quantities except for the special case when the ac current and voltage are restricted to perfect sine waves and the load is a pure resistance.

\[ P_{\text{inst}} = ei \quad (40.1a) \]

In real-world situations where current and/or voltage waveforms are not perfectly sinusoidal and/or the loads are other than resistive, the relationships are no longer simple and the power delivered, or active power, is usually less than the product of rms voltage and current, as shown in Equation 40.2.
The product of rms voltage and rms current does, however, define a quantity termed *apparent power*, $U$, as shown in Equation 40.3.

$$U = E_{\text{rms}} I_{\text{rms}} \quad (40.3)$$

A derived term, the *power factor*, $F_p$, used to express the relationship between delivered or active power, $P$, and apparent power, $U$, is defined by Equation 40.4.

$$F_p = \frac{P}{U} \quad (40.4)$$

From Equations 40.2, 40.3, and 40.4, it is clear that the value of $F_p$ must lie in a range between zero and one.

This chapter focuses on: (1) ac power relationships and the calculation of power factor; (2) the physical meaning of these relationships; and (3) measurement techniques and instrumentation for determining these relationships and calculating power factor.

### 40.1 Reasons for Interest in Power Factor

Power factor is a single number that relates the active power, $P$, to the apparent power, $U$. Electric components of a utility distribution system are designed on a kVA basis; i.e., they are designed to operate...
at a given voltage and carry a rated current without undue temperature rise. Transformer and conductor sizes are chosen on this basis. While active power does useful work, reactive and harmonic powers do no useful work, absorb system capacity, and increase system losses; but reactive and harmonic powers are needed to provide magnetic fields or nonlinear currents. *The capacity of electric systems is limited by apparent power, not active power.* Power factor expresses, with a single value, the extent to which an electrical distribution system is efficiently and effectively utilized. A low value for the power factor means that much of the system capacity is not available for useful work. From a utility viewpoint, this means reduced ability to deliver revenue-producing active power; from a user viewpoint, a low power factor reduces the available active power or requires increased system size to deliver needed power.

### 40.2 ac Electric Loads

#### Linear Loads

Electric loads in ac power systems with sinusoidal voltages are categorized by the way they draw current from the system. Loads that draw sinusoidal currents, i.e., the current waveshape is the same as the voltage waveshape, are defined as *linear loads.* Historically, a high percentage of electric loads have been linear. Linear loads include: (1) induction motors; (2) incandescent lighting; and (3) heaters and heating elements. Linear loads use ac electric power directly to accomplish their functions.

#### Nonlinear Loads

Electric loads that draw nonsinusoidal currents, i.e., the current waveshape differs from the voltage waveshape, are defined as *nonlinear loads.* As energy savings and efficient use of electricity are emphasized, an increased percentage of nonlinear electric devices, both new and replacement, are being installed. Nonlinear loads include: (1) adjustable-speed motor drives; (2) fluorescent and arc-discharge lighting; (3) computers and computerized controls; and (4) temperature-controlled furnaces and heating elements. Nonlinear loads, rather than using ac electric power directly, often convert ac power into direct current before it is used to accomplish their functions. A common element in nonlinear loads is some kind of rectifier to accomplish this ac to dc conversion. Rectifiers do not draw sinusoidal currents.

### 40.3 ac Power Relationships

#### Sinusoidal Voltage and Current

Power calculations for sinusoidal ac electric systems require knowledge of the rms voltage, the rms current, and the phase relationships between the two. Figure 40.2 illustrates possible phase relationships between voltage and current. If the positive-going zero-crossing of the voltage is considered the reference point, then the nearest positive-going zero-crossing of the current can occur at a wave angle either less than or greater than this reference. If the current zero-crossing occurs before the reference, the current is said to *lead* the voltage. If the current zero-crossing occurs after the reference, the current is *lagging.* If the zero-crossing for the current coincides with the reference, the two waves are said to be *in phase.* The wave angle, $\theta$, by which the current leads or lags the voltage is called the *phase angle,* in this case, $30^\circ$.

#### Single-Phase Circuits

**Power Calculations**

The power delivered to do work is easily calculated [1]. Given a sinusoidal voltage of rms magnitude $E$ and sinusoidal current of rms magnitude $I$, displaced by angle $\theta$, at time $t$, 

© 1999 by CRC Press LLC
Equation 40.5 is the fundamental equation that defines power for systems in which the current and voltage are sinusoidal. The application of this equation is illustrated for three cases: (1) the current and voltage are in phase; (2) the current and voltage are out of phase by an angle less than 90°; and (3) the current and voltage are out of phase by exactly 90°.

\[
\text{Instantaneous voltage} = e \sqrt{2} E \sin(2\pi ft)
\]

\[
\text{Instantaneous current} = i = \sqrt{2} I \sin(2\pi ft - \theta) \quad \text{(note that } \theta \text{ can have a positive or negative value)}
\]

\[
\text{Instantaneous power} = p = ei
\]

\[
p = 2EI \sin(2\pi ft) \sin(2\pi ft - \theta)
\]

\[
p = EI \cos(\theta) - EI \cos(4\pi ft - \theta)
\]

Average power over an integral number of cycles \( P = EI \cos(\theta) \) \hspace{1cm} (40.5)

Power factor \( F_p = \frac{P}{U} = \frac{EI \cos(\theta)}{EI} = \cos(\theta) \) \hspace{1cm} (40.5)

Equation 40.5 is the fundamental equation that defines power for systems in which the current and voltage are sinusoidal. The application of this equation is illustrated for three cases: (1) the current and voltage are in phase; (2) the current and voltage are out of phase by an angle less than 90°; and (3) the current and voltage are out of phase by exactly 90°.

FIGURE 40.2  Sine wave phase angle. Two waves with the same zero-crossing are in phase. A sine wave that crosses zero before the reference wave is leading, and one that crosses zero after the reference wave is lagging. The phase angle \( \theta \) illustrated is 30° lagging.
Ac Power Examples

Figure 40.3 shows voltage current and power when the voltage and current are in phase and the current displacement angle is zero (0°). (An example would be a resistance space heater.) The power curve is obtained by multiplying together the instantaneous values of voltage and current as the wave angle is varied from 0° to 360°. Instantaneous power, the product of two sine waves, is also a sine wave. There are two zero-crossings per cycle, dividing the cycle into two regions. In region (1) both the voltage and current are positive and the resultant product, the power, is positive. In region (2) both the voltage and current are negative and the power is again positive. The average power in watts, given by Equation 40.5, \[ \text{EI} \cos(0°) = \text{EI} \], is the maximum power that can be delivered to do work. When sinusoidal voltage and current are in phase, the delivered power in watts is the same as for dc and is the maximum that can be delivered. The power factor, \( F_p = \cos(0°) = 1 \), or unity.

Figure 40.4 shows voltage, current, and power when the current lags the voltage by 60°. (An example might be a lightly loaded induction motor.) The power sine wave again is obtained by multiplying together the instantaneous values of voltage and current. There are now four zero-crossings per cycle, dividing the cycle into four regions. In regions (2) and (4), voltage and current have the same sign and the power is positive. In regions (1) and (3), voltage and current have opposite signs, resulting in a negative value for the power. The average power in watts, given by Equation 40.5, \[ \text{Ekos}(60°) = EI(0.5) \], is less than the maximum that could be delivered for the particular values of voltage and current. When voltage and current are out of phase, the delivered power in watts is always less than the maximum. In this example, \( F_p = \cos(60°) = 0.5 \).

Figure 40.5 shows voltage, current, and power when the current lags the voltage by 90°. (This situation is not attainable in the real world.) The power sine wave again is obtained by multiplying together the instantaneous values of voltage and current. Again, four zero-crossings divide the cycle into four regions.
FIGURE 40.4 Voltage, current, and power for sine waves $60^\circ$ out of phase. The vertical scales for voltage and current amplitudes are the same as those for Figure 40.3. Current lags voltage by $60^\circ$ and both are sinusoidal. The power is positive in regions (2) and (4), and negative in regions (1) and (3). Average power delivered to do work is less than the maximum power.

FIGURE 40.5 Voltage, current, and power for sine waves $90^\circ$ out of phase. The vertical scales for voltage and current amplitudes are the same as those for figure 40.3. Current lags voltage by $90^\circ$ and both are sinusoidal. The power is positive in regions (2) and (4), negative in regions (1) and (3), and is of equal absolute magnitude in all four regions. Average power delivered to do work is zero.
In regions (2) and (4), the power is positive, while in regions (1) and (3), the power is negative. The average power in watts is given by Equation 40.5, \( EI \cos(\theta) = 0 \). No matter what the values of voltage and current, when voltage and current are exactly 90° out of phase, the delivered power in watts is always zero. The power factor, \( F_p = \cos(90°) = 0 \).

**Power Factor**

Resolving the current into orthogonal components on a phasor diagram illustrates how delivered power can vary from a maximum to zero, depending on the phase angle between the voltage and the current sine waves. Figure 40.6 shows the voltage vector along with the current resolved into orthogonal components [1]. The current \( I \) at an angle \( \theta \) relative to the voltage can be resolved into two vectors: \( I \cos(\theta) \) and \( I \sin(\theta) \). The in-phase component \( I \cos(\theta) \) multiplied by the voltage gives average power in watts. The current component that is 90° out of phase with the voltage, \( I \sin(\theta) \), is not associated with delivered power and does not contribute to work. For want of a better name, this was often termed the "wattless component" of the current. Since this wattless current could be associated with magnetic fields, it was sometimes termed "magnetizing current" because, while doing no work, this current interacts through the inductive reactance of an ac motor winding to provide the magnetic field required for such a motor to operate.

Three types of power have been defined for systems in which both the voltage and current are sinusoidal. Throughout the years, a number of different names have been given to the three power types. The names in present usage will be emphasized.

**Active power** is given the symbol \( P \) and is defined by Equation 40.5:

\[
P = EI \cos(\theta)
\]  

(40.5)

Other names for active power include: (1) real power and (2) delivered power. Active power is the power that does work. Note that while all power quantities are volt-ampere products, only **active power is expressed in watts**.

**Reactive power** is given the symbol \( Q \) and is defined by the equation:

\[
Q = EI \sin(\theta)
\]  

(40.6)

Other names for reactive power include: (1) imaginary power; (2) wattless power; (3) and magnetizing power. Reactive power is expressed in volt-amperes\(_{\text{reactive}}\) or vars. If the load is predominantly inductive, current lags the voltage and the reactive power is given a positive sign. If the load is predominantly capacitive, current leads the voltage and the reactive power is given a negative sign.

**Phasor power** is given the symbol \( S \) and is defined by the equation:

\[
S = \sqrt{P^2 + Q^2}
\]  

(40.7)
Phasor power was called apparent power for many years, and it will be seen in a later section that phasor power $S$, for sinusoidal voltages and currents, is identical to what is now called apparent power $U$. Phasor power is expressed in voltamperes or VA.

Figure 40.7 is a phasor diagram, often called a power triangle, which illustrates the relationships among the three types of power defined above. Reactive power is orthogonal to active power, and is shown as positive for lagging current. It is clear that the definition of phasor power, Equation 40.7, is geometrically derived from active and reactive power.

Power factor is given the symbol $F_p$ and for sinusoidal quantities is defined by the equation:

$$F_p = \frac{\text{ACTIVE POWER}}{\text{PHASOR POWER}} = \frac{P}{S} = \frac{\text{WATTS}}{\text{VOLTAMPS}} = \cos\theta \quad (40.8)$$

Since the power factor can be expressed in reference to the displacement angle between voltage and current, power factor so defined should be termed displacement power factor, and the symbol is often written $F_p$ displacement. Values for displacement power factor range from one (unity) to zero as the current displacement angle varies from 0° (current and voltage in phase) to 90°. Since the cosine function is positive in both the first and fourth quadrants, the power factor is positive for both leading and lagging currents. To completely specify the voltage–current phase relationship, the words leading or lagging must be used in conjunction with power factor. Power factor can be expressed as a decimal fraction or as percent. For example, the power factor of the case shown in Figure 40.4 is expressed either as 0.5 lagging or 50% lagging.

**Polyphase Circuits**

**Power Calculations**

The power concepts developed for single-phase circuits with sinusoidal voltages and currents can be extended to polyphase circuits. Such circuits can be considered to be divided into a group of two-wire sets, with the neutral conductor (or a resistively derived neutral for the case of a delta-connected, three-wire circuit) paired with each other conductor. Equations 40.3–40.5 can be rewritten to define power terms equivalent to the single-phase terms. In these equations, $k$ represents a phase number, $m$ is the total number of phases, and $\alpha$ and $\beta$ are, respectively, the voltage and current phase angles with respect to a common reference frame.

$$P = \sum_{k=1}^{m} E_k I_k \cos(\alpha - \beta) \quad (40.9)$$

$$Q = \sum_{k=1}^{m} E_k I_k \sin(\alpha - \beta) \quad (40.10)$$
and, restating Equation 40.7:

\[ S = \sqrt{P^2 + Q^2} \]

For example, a three-phase sinusoidal power distribution service, with phases a, b, and c:

\[
\begin{align*}
P &= E_a I_a \cos(\alpha_a - \beta_a) + E_b I_b \cos(\alpha_b - \beta_b) + E_c I_c \cos(\alpha_c - \beta_c) \\
Q &= E_a I_a \sin(\alpha_a - \beta_a) + E_b I_b \sin(\alpha_b - \beta_b) + E_c I_c \sin(\alpha_c - \beta_c) \\
S &= \sqrt{P^2 + Q^2}
\end{align*}
\]

**Power Factor**

Power factor is defined by Equation 40.11. Note that it is no longer always true to say that power factor is equal to the cosine of the phase angle. In many three-phase balanced systems, the phase angles of all three phases are equal and the cosine relationship holds. In unbalanced systems, such as that represented by the phasor diagram Figure 40.8, each phase has a different phase angle, the phase voltages and currents are not equal, and the cosine relationship fails [3].

\[
F_p = \frac{\text{TOTAL ACTIVE POWER}}{\text{PHASOR POWER}} = \frac{P_{\text{eq}}}{S} = \frac{\text{WATTS}}{\text{VOLTAMPS}} \quad \text{often} \neq \cos \theta \quad (40.11)
\]

**Nonsinusoidal Voltage and Current**

**Fourier Analysis**

Figure 40.9 shows voltage, current, and power for a typical single-phase nonlinear load, a computer switch-mode power supply. Due to the nature of the bridge rectifier circuit in this power supply, current is drawn from the line in sharp spikes. The current peak is only slightly displaced from the voltage peak and the power is everywhere positive. However, power is delivered to the load during only part of the cycle and the average power is much lower than if the current had been sinusoidal. The current waveshape
required by the load presents a problem to the ac power system, which is designed to deliver only sine wave current. The solution to this problem is based on mathematical concepts developed in 1807 for describing heat flow by Jean Baptiste Joseph Fourier, a French mathematician [4]. Fourier’s theorem states that any periodic function, however complex, can be broken up into a series of simple sinusoids, the sum of which will be the original complex periodic variation. Applied to the present electrical problem, Fourier’s theorem can be stated: any periodic nonsinusoidal electrical waveform can be broken up into a series of sinusoidal waveforms, each a harmonic of the fundamental, the sum of which will be the original nonsinusoidal waveform.

Harmonics

Harmonics are defined as continuous integral multiples of the fundamental waveform. Figure 40.10 shows a fundamental sine wave and two harmonic waves — the 3rd and 5th harmonics. The harmonic numbers 3 and 5 express the number of complete cycles for each harmonic wave per cycle of the fundamental (or 1st harmonic). Each harmonic wave is defined by its harmonic number, its amplitude, and its phase relationship to the fundamental. Note that the fundamental frequency can have any value without changing the harmonic relationships, as shown in Table 40.1.

Power Calculations

Calculating power delivered to do work for a nonlinear load is somewhat more complicated than if the current were sinusoidal. If the fundamental component of the voltage at frequency \( f \) is taken as a reference (the a-phase fundamental for a polyphase system), the subscript “1” means the fundamental, and \( E \) denotes the peak value of the voltage; then the voltage can be expressed as:

\[
\varepsilon_{a1(t)} = E_{a1} \sin(2\pi ft + \theta)
\]
The voltage fundamental will then have an amplitude $E_{a1}$ and pass through zero in the positive going direction at time $t = 0$. If $h = \text{harmonic number}$, and $E_h$ and $I_h$ are peak amplitudes of the harmonic voltage and current, respectively, then general expressions for any harmonic will be:

$$e_{h(t)} = E_h \sin \left(2\pi f_h t + \alpha_h^\circ \right)$$

$$i_{h(t)} = I_h \sin \left(2\pi f_h t + \beta_h^\circ \right)$$

To compute the power associated with a voltage and current waveform, take advantage of the fact that products of harmonic voltages and currents of different frequency have a time average of zero. Only products of voltages and currents of the same frequency are of interest, giving a general expression for harmonic power as:

$$p_{h(t)} = E_h I_h \sin \left(2\pi f_h t + \alpha_h^\circ \right) \sin \left(2\pi f_h t + \beta_h^\circ \right)$$

**FIGURE 40.10** Harmonics are continuous integral multiples of the fundamental frequency. The 5th harmonic is shown, in phase with the fundamental, while the 3rd harmonic is $180^\circ$ out of phase.

**TABLE 40.1** Harmonics and Their Relationship to the Fundamental Frequency

The voltage fundamental will then have an amplitude $E_{a1}$ and pass through zero in the positive going direction at time $t = 0$. If $h = \text{harmonic number}$, and $E_h$ and $I_h$ are peak amplitudes of the harmonic voltage and current, respectively, then general expressions for any harmonic will be:
Simplifying with trigonometric identities, evaluating over an integral number of cycles, and replacing peak voltage and current with rms values, the average power becomes:

\[ P_{h} = E_{h} I_{h} \cos(\alpha_{h} - \beta_{h}) \]

For a single-phase system where \( h \) is the harmonic number and \( H \) is the highest harmonic, the total average power or active power is given by:

\[ P = \sum_{h=1}^{H} E_{h} I_{h} \cos(\alpha_{h} - \beta_{h}) \]  \hspace{1cm} (40.12)

Total average reactive power is given by:

\[ Q = \sum_{h=1}^{H} E_{h} I_{h} \sin(\alpha_{h} - \beta_{h}) \]  \hspace{1cm} (40.13)

It should be noted that in the real world, the actual contribution of harmonic frequencies to active and reactive power is small (usually less than 3% of the total active or reactive power). The major contribution of harmonic frequencies to the power mix comes as distortion power, which will be defined later.

For a polyphase system wherein \( r \) is the phase identification and \( N \) is the number of conductors in the system, including the neutral conductor, total average power for a polyphase system is given by:

\[ P = \sum_{r=1}^{N} \sum_{h=1}^{H} E_{r_{h}} I_{r_{h}} \cos(\alpha_{r_{h}} - \beta_{r_{h}}) \]  \hspace{1cm} (40.14)

Total average reactive power is given by:

\[ Q = \sum_{r=1}^{N} \sum_{h=1}^{H} E_{r_{h}} I_{r_{h}} \sin(\alpha_{r_{h}} - \beta_{r_{h}}) \]  \hspace{1cm} (40.15)

**Power Factor**

**Single-Phase Systems**

For a single-phase system, phasor power is again given by Equation 40.7 and illustrated by Figure 40.7, where \( P \) is the algebraic sum of the active powers for the fundamental and all the harmonics (Equation 40.12), and \( Q \) is the algebraic sum of the reactive powers for the fundamental and all the harmonics (Equation 40.13). Therefore, phasor power is based on the fundamental and harmonic active and reactive powers. It is found, however, that phasor power \( S \) is no longer equal to apparent power \( U \) and a new power phasor must be defined to recognize the effects of waveform distortion. A phasor representing the distortion, termed *distortion power* and given the symbol \( D \), is defined by:

\[ D = \pm \sqrt{U^2 - S^2} \]  \hspace{1cm} (40.16)

Without further definite information as to the sign of distortion power, its sign is selected the same as the sign of the total active power. The relationships among the various power terms are displayed in
Figure 40.11, a 3-dimensional phasor diagram. Power factor, in direct parallel with sinusoidal waveforms, is defined by the equation:

\[
F_p = \frac{\text{TOTAL ACTIVE POWER}}{\text{APPARENT POWER}} = \frac{P}{U} = \frac{\text{WATTS}}{\text{VOLTAMPS}} \quad (40.17)
\]

From Equations 40.7 and 40.16 we obtain:

\[
S = \sqrt{P^2 + Q^2} \quad (40.7)
\]

\[
U = \sqrt{S^2 + D^2} = \sqrt{P^2 + Q^2 + D^2} \quad (40.18)
\]

It is clear that when waveforms are sinusoidal, i.e., linear loads are drawing current, that there is no distortion power and Equation 40.18 reduces to Equation 40.7. Likewise as shown in Figure 40.13, as the distortion power vector goes to zero, the figure becomes two-dimensional and reduces to Figure 40.7, and \( U \) becomes equal to \( S \). When, however, nonlinear loads are drawing harmonic currents from the system, \( U \) will be greater than \( S \). As already noted, the contribution of the harmonics to the total power quantities is small and one is frequently interested mainly in the fundamental quantities.

The power factor associated only with the fundamental voltage and current components was termed the displacement power factor \( F_p \text{ displacement} \), where Equations 40.7 and 40.8 are written [5]:

\[
S_{60} = \sqrt{P_{60}^2 + Q_{60}^2}
\]

and

\[
F_p \text{ displacement} = \frac{P_{60}}{S_{60}}
\]

When harmonics are present, \( F_p \) is always smaller than \( F_p \text{ displacement} \).
For a polyphase system, phasor power, $S$, is again given by Equation 40.7, but one must now use the total values for $P$ and $Q$ calculated using Equations 40.14 and 40.15. One can then define the apparent power in two ways.

- **Arithmetic apparent power.** The arithmetic apparent power is given the symbol $U_A$, and is defined by Equation 40.19, where $E_r$ and $I_r$ are the rms values for the respective phases and $M$ equals the number of phases. $U_A$ is a scalar quantity.

$$U_A = \sum_{r=1}^{M-1} E_r I_r$$  \hspace{1cm} (40.19)

- **Apparent power.** Apparent power is given the symbol $U$, and is defined by Equation 40.18 using total values for $P$ and $Q$ as defined by Equations 40.14 and 40.15, and a total value for $D$ determined using Equation 40.16 for each phase. Figure 40.12 illustrates the two alternative concepts for polyphase apparent power [6]. Note that $U_r$ uses arithmetic addition of vector magnitudes and is equal to apparent power $U$ only if the polyphase voltages and currents have equal magnitudes and equal angular spacings, a situation that often exists in balanced three-phase systems. The two alternative definitions of apparent power, $U$ and $U_A$, give rise to two possible values for power factor: (1) $F_p = P/U$ and (2) $F_{pa} = P/U_A$. Apparent power $U$ and power factor $F_p$ are the preferred definitions since using $U_A$ can give unexpected results with some nonsymmetric service arrangements such as four-wire delta, and, with extremely unbalanced resistive loads, $F_{pa}$ can exceed 1.0. Despite these shortcomings, arithmetic apparent power has become quite widely used due to the comparative simplicity of its measurement and calculation. With the advent of sophisticated digital meters, there is no longer any advantage to using arithmetic apparent power and its use will surely decrease.
40.4 Power Factor “Measurement”

There are no instruments that measure power factor directly. (Power stations and large substations often use phase angle meters with a power factor scale representing $\cos(\theta)$ to display power factor. Such meters are accurate only for sinusoidal balanced polyphase systems.) One must remember that, of all the ac power quantities discussed, the only ones that can be directly measured are voltages, currents, and their time relationships (phase angles). All other ac power quantities are derived mathematically from these measured quantities. The only one of these derived values that has physical reality is the active power $P$ (the quantity that does work); the others are mathematical constructs. Therefore, correct determination of power factor requires accurate measurement of voltage and current, and proficient mathematics.

Metering for Linear Loads

By the early 1920s, the concepts of active, reactive, and apparent (since renamed phasor) power, and power factor were known, and metering capabilities had been developed to enable their determination. Energy meters utilizing voltage and current coils driving an induction disk inherently measured active power $P (E_1 \cos \theta)$, which was displayed on a mechanical register. Using the trigonometric identity $E_1 \sin \theta = E_1 \cos(90^\circ + \theta)$, with voltage delayed $90^\circ$, a similar energy meter displayed reactive power $Q$ and, with these two values, displacement power factor was calculated. Voltage delay (phase shifting) was accomplished using specially wound transformers.

Through the years, the method of obtaining the $90^\circ$ phase shift has been updated. Analog electronic meters are available that provide the $90^\circ$ phase shift electronically within the meter. More recently, digital meters have been developed that sample voltages and currents at regular intervals and digitize the results. Voltages and currents are multiplied as they are captured to compute active power. Past voltage samples delayed by a time equal to a quarter cycle ($90^\circ$) are multiplied by present current values to obtain reactive power. Active–reactive metering of this type is a widely utilized method for determining displacement power factor for utility billing. These meters do not accurately measure the effect of harmonic currents because the delay of the voltage samples is based on the fundamental frequency and is incorrect for the harmonics. (The important $5^{th}$ harmonic, which is frequently the predominant harmonic component, is accurately measured because it is delayed $450^\circ$ ($5 \times 90^\circ$), which is equivalent to the correct $90^\circ$ delay).

Metering for Nonlinear Loads

With the application of high-speed digital computing techniques to measurement of ac currents and voltages, together with digital filtering, the quantities necessary for accurate and correct calculation of power factor are susceptible to direct computation. In practice, the ac waveforms are sampled at a frequency greater than twice the highest frequency to be measured, in compliance with well-known sampling theories. Data obtained can be treated using Fourier’s equations to calculate rms values for voltage, current, and phase angle for the fundamental and each harmonic frequency. Power quantities can be obtained with digital filtering in strict accordance with their ANSI/IEEE STD 100 definitions.

Power quantities can be displayed for the fundamental only (displacement power factor), or for fundamental plus all harmonics (power factor for nonsinusoidal waveforms).

Metering Applications

Instruments with the capabilities described above are often called harmonic analyzers, and are available in both single-phase and polyphase versions. They can be portable, in which case they are often used for power surveys, or panel mounted for utility and industrial revenue metering. Polyphase analyzers can be connected as shown in Figures 40.13 and 40.14. Care must be taken to connect the instrument properly. Both voltage leads and current transformers must be connected to the proper phases, and the current transformers must also be placed with the correct polarity. Most instruments use color-coded voltage connectors. Correct polarity is indicated on the current transformers by arrows or symbols, and complete
hook-up and operating instructions are included. When single-phase instruments are used, the same precautions must be followed for making connections.

40.5 Instrumentation

Table 40.2 lists a sampling of harmonic and power factor measuring instruments available from major manufacturers. All instruments listed use some type of Fourier calculations and/or digital filtering to determine power values in accordance with accepted definitions. Many can be configured to measure non-harmonic-related power quality concerns. Unless otherwise noted, all instruments require the purchase of one current probe per input. Probes are available for measuring currents from 5 A to several thousand amperes. For comparison purposes, priced probes will be those with a 600-A range. Voltage leads are usually supplied as standard equipment. Table 40.3 contains addresses of these manufacturers.

Defining Terms

**Active power:** A term used to express the real power delivered to do work in an ac distribution system.

**Reactive power:** A term used to express the imaginary power that does no work but provides magnetization to enable work in an ac distribution system.

**Phasor power:** A term used to express the product of volts and amperes in an ac distribution system in which voltage and current are sinusoidal.

**Harmonic power:** A term used to express the power due to harmonic frequencies in an ac distribution system in which voltage and/or current are nonsinusoidal.

**Apparent power:** A term used to express the product of volts and amperes in an ac distribution system in which voltage and/or current are nonsinusoidal.

**Power factor:** A single number, calculated by dividing active power by either the phasor power or the apparent power, which describes the effective utilization of ac distribution system capacity.

41.6 Instrumentation and Components

The notion of “phase” is usually associated with periodic or repeating signals. With these signals, the waveshape perfectly repeats itself every time the period of repetition elapses. For periodic signals one can think of the phase at a given time as the fractional portion of the period that has been completed. This is commonly expressed in degrees or radians, with full cycle completion corresponding to 360° or 2π radians. Thus, when the cycle is just beginning, the phase is zero. When the cycle is half completed, the phase is half of 360°, or 180° (See Figure 41.1). It is important to note that if phase is defined as the portion of a cycle that is completed, the phase depends on where the beginning of the cycle is taken to be. There is no universal agreement on how to specify this beginning. For a sinusoidal signal, probably the two most common assumptions are that the start of the cycle is (1) the point at which the maximum value is achieved, and (2) the point at which the negative to positive zero-crossing occurs. Assumption (1) is common in many theoretical treatments of phase, and for that reason is adopted in this chapter. It should be noted, however, that assumption (2) has some benefits from a measurement perspective, because the zero-crossing position is easier to measure than the maximum.

The measurement of phase is important in almost all applications where sinusoids proliferate. Many means have therefore been devised for this measurement. One of the most obvious measurement techniques is to directly measure the fractional part of the period that has been completed on a cathode-ray oscilloscope (CRO). Another approach, which is particularly useful when a significant amount of noise is present, is to take the Fourier transform of the signal. According to Fourier theory, for a sinusoidal signal, the energy in the Fourier transform is concentrated at the frequency of the signal; the initial phase of the signal (i.e., the phase at time, \( t = 0 \)) is the phase of the Fourier transform at the point of this energy concentration. The measurements of initial phase and frequency obtained from the Fourier transform can then be used to deduce the phase of the signal for any value of time.
Frequently what is needed in practice is a measurement of the phase difference between two signals of the same frequency; that is, it is necessary to measure the relative phase between two signals rather than the absolute phase of either one (see Figure 41.2). Often, in the measurement of the relative phase between two signals, both signals are derived from the same source. These signals might, for example, be the current and voltage of a power system; the relative phase, $\phi$, between the current and voltage would then be useful for monitoring power usage, since the latter is proportional to the cosine of $\phi$.

Several techniques are available for the measurement of “relative phase.” One crude method involves forming “Lissajous figures” on an oscilloscope. In this method, the first of the two signals of interest is fed into the vertical input of a CRO and the other is fed into the horizontal input. The result on the oscilloscope screen is an ellipse, the intercept and maximum height of which can be used to determine the relative phase. Other methods for determining relative phase include the crossed-coil meter (based on electromagnetic induction principles), the zero-crossing phase meter (based on switching circuitry for determining the fractional portion of the period completed), the three-voltmeter method (based on the use of three signals and trigonometric relationships), and digital methods (based on analog-to-digital conversion and digital processing).
41.1 Amplitude, Frequency, and Phase of a Sinusoidal Signal

An arbitrary sinusoidal signal can be written in the form:

\[ s(t) = A \cos(2\pi ft + \phi_0) = A \cos(\omega t + \phi_0) \]  (41.1)

where 
- \( A \) = Peak amplitude
- \( f \) = Frequency
- \( \omega \) = Angular frequency
- \( \phi_0 \) = Phase at time \( t = 0 \)

This signal can be thought of as being the real part of a complex phasor that has amplitude, \( A \), and which rotates at a constant angular velocity \( \omega = 2\pi f \) in the complex plane (see Figure 41.3).

Mathematically, then, \( s(t) \) can be written as:

\[ s(t) = \Re\{Ae^{j(2\pi ft + \phi_0)}\} = \Re\{z(t)\} \]  (41.2)

where \( z(t) \) is the complex phasor associated with \( s(t) \), and \( \Re\{\cdot\} \) denotes the real part. The “phase” of a signal at any point in time corresponds to the angle that the rotating phasor makes with the real axis. The initial phase (i.e., the phase at time \( t = 0 \)) is \( \phi_0 \). The “frequency” \( f \) of the signal is \( 1/2\pi \) times the phasor’s angular velocity.
There are a number of ways to define the phase of a real sinusoid with unknown amplitude, frequency, and initial phase. One way, as already discussed, is to define it as the fractional part of the period that has been completed. This is a valid and intuitively pleasing definition, and one that can be readily generalized to periodic signals that contain not only a sinusoid, but also a number of harmonics. It cannot, however, be elegantly generalized to allow for slow variations in the frequency of the signal, a scenario that occurs in communicatons with phase and frequency modulation. Gabor put forward a definition in 1946 that can be used for signals with slowly varying frequency. He proposed a mathematical definition for generating the complex phasor, $z(t)$, associated with the real signal, $s(t)$. The so-called analytic signal $z(t)$ is defined according to the following definition [1]:

$$z(t) = s(t) + j\mathcal{H}\{s(t)\}$$  \hspace{1cm} (41.3)

where $\mathcal{H}\{\cdot\}$ denotes the Hilbert transform and is given by:

$$\mathcal{H}\{s(t)\} = p.v. \left[ \int_{-\infty}^{+\infty} \frac{s(t-\tau)}{\pi \tau} d\tau \right]$$  \hspace{1cm} (41.4)

with p.v. signifying the Cauchy principal value of the integral [2].

The imaginary part of the analytic signal can be generated practically by passing the original signal through a “Hilbert transform” filter. From Equations 41.3 and 41.4, it follows that this filter has impulse response given by $1/\pi \tau$. The filter can be implemented, for example, with one of the HSP43xxx series of ICs from Harris Semiconductors. Details of how to determine the filter coefficients can be found in [2].

Having formally defined the analytic signal, it is possible to provide definitions for phase, frequency, and amplitude as functions of time. They are given below.

---

FIGURE 41.3 A complex rotating phasor, $A \exp(j\omega t + \phi_0)$. The length of the phasor is $A$ and its angular velocity is $\omega$. The real part of the phasor is $A \cos(\omega t + \phi_0)$. 

The imaginary part of the phasor is $A \sin(\omega t + \phi_0)$. This diagram illustrates the concept of a complex phasor in the plane of real and imaginary parts, with the position of the phasor at time $t=0$ and at any time $t$. The phasor's length represents the amplitude $A$, the angle $\phi_0$ is the initial phase, and the angular velocity $\omega$ determines the rate of rotation.
Phase: \( \phi(t) = \arg\{z(t)\} \) \hspace{1cm} (41.5)

Frequency: \( f(t) = \frac{1}{2\pi} \frac{d}{dt} \arg\{z(t)\} \) \hspace{1cm} (41.6)

Amplitude: \( A(t) = \text{abs}\{z(t)\} \) \hspace{1cm} (41.7)

The definitions for phase, frequency, and amplitude can be used for signals whose frequency and/or amplitude vary slowly with time. If the frequency and amplitude do vary with time, it is common to talk about the “instantaneous frequency” or “instantaneous amplitude” rather than simply the frequency or amplitude.

Note that in the analytic signal, the imaginary part lags the real part by 90°. This property actually holds not only for sinusoids, but for the real and imaginary parts of all frequency components in “multicomponent” analytic signals as well. The real and imaginary parts of the analytic signal then correspond to the “in-phase (I)” and “quadrature (Q)” components used in communications systems.

In a balanced three-phase electrical power distribution system, the analytic signal can be generated by appropriately combining the different outputs of the electrical power signal; that is, it can be formed according to:

\[
z(t) = v_a(t) + \frac{1}{\sqrt{3}} \left[ v_b(t) - v_c(t) \right]
\]

where

- \( v_a(t) \) = Reference phase
- \( v_b(t) \) = Phase that leads the reference by 120°
- \( v_c(t) \) = Phase that lags the reference by 120°.

41.2 The Phase of a Periodic Nonsinusoidal Signal

It is possible to define “phase” for signals other than sinusoidal signals. If the signal has harmonic distortion components present in addition to the fundamental, the signal will still be periodic, but it will no longer be sinusoidal. The phase can still be considered to be the fraction of the period completed. The “start” of the period is commonly taken to be the point at which the initial phase of the fundamental component is 0, or at a zero-crossing. This approach is equivalent to just considering the phase of the fundamental, and ignoring the other components. The Fourier method provides a very convenient method for determining this phase — the energy of the harmonics in the Fourier transform can be ignored.

41.3 Phase Measurement Techniques

Direct Oscilloscope Methods

Cathode-ray oscilloscopes (CROs) provide a simple means for measuring the phase difference between two sinusoidal signals. The most straightforward approach to use is direct measurement; that is, the signal of interest is applied to the vertical input of the CRO and an automatic time sweep is applied to the horizontal trace. The phase difference is the time delay between the two waveforms measured as a fraction of the period. The result is expressed as a fraction of 360° or of \( 2\pi \) radians; that is, if the time
delay is 1/4 of the period, then the phase difference is 1/4 of 360° = 90° (see Figure 41.2). If the waveforms are not sinusoidal but are periodic, the same procedure can still be applied. The phase difference is just expressed as a fraction of the period or as a fractional part of 360°.

Care must be taken with direct oscilloscope methods if noise is present. In particular, the noise can cause triggering difficulties that would make it difficult to accurately determine the period and/or the time delay between two different waveforms. The “HF reject” option, if available, will alleviate the triggering problems.

Lissajous Figures

Lissajous figures are sometimes used for the measurement of phase. They are produced in an oscilloscope by connecting one signal to the vertical trace and the other to the horizontal trace. If the ratio of the first frequency to the second is a rational number (i.e., it is equal to one small integer divided by another), then a closed curve will be observed on the CRO (see Figures 41.4 and 41.5). If the two frequencies are unrelated, then there will be only a patch of light observed because of the persistence of the oscilloscope screen.

If the two signals have the same frequency, then the Lissajous figure will assume the shape of an ellipse. The ellipse’s shape will vary according to the the phase difference between the two signals, and according to the ratio of the amplitudes of the two signals. Figure 41.6 shows some figures for two signals with synchronized frequency and equal amplitudes, but different phase relationships. The formula used for determining the phase is:

\[
\sin(\phi) = \pm \frac{Y}{H}
\]

where \( H \) is half the maximum vertical height of the ellipse and \( Y \) is the intercept on the \( y \)-axis. Figure 41.7 shows some figures for two signals that are identical in frequency and have a phase difference of 45°, but with different amplitude ratios. Note that it is necessary to know the direction that the Lissajous trace is moving in order to determine the sign of the phase difference. In practice, if this is not known a priori,
then it can be determined by testing with a variable frequency signal generator. In this case, one of the signals under consideration is replaced with the variable frequency signal. The signal generator is adjusted until its frequency and phase equal that of the other signal input to the CRO. When this happens, a straight line will exist. The signal generator frequency is then increased a little, with the relative phase
thus being effectively changed in a known direction. This can be used to determine the correct sign in Equation 41.9.

Lissajous figure methods are a little more robust to noise than direct oscilloscope methods. This is because there are no triggering problems due to random noise fluctuations. Direct methods are, however, much easier to interpret when harmonics are present. The accuracy of oscilloscope methods is comparatively poor. The uncertainty of the measurement is typically in excess of 1°.

**Zero-Crossing Methods**

This method is currently one of the most popular methods for determining phase difference, largely because of the high accuracy achievable (typically 0.02°). The process is illustrated in Figure 41.8 for two signals, denoted A and B, which have the same frequency but different amplitudes. Each negative to positive zero-crossing of signal A triggers the start of a rectangular pulse, while each negative to positive zero-crossing of signal B triggers the end of the rectangular pulse. The result is a pulse train with a pulse width proportional to the phase angle between the two signals. The pulse train is passed through an averaging filter to yield a measure of the phase difference. It is also worth noting that if the positive to negative zero-crossings are also used in the same fashion, and the two results are averaged, the effects of dc and harmonics can be significantly reduced.

To implement the method practically, the analog input signals must first be converted to digital signals that are "high" if the analog signal is positive, and "low" if the analog signal is negative. This can be done, for example, with a Schmitt trigger, along with an RC stabilizing network at the output. Chapter 81 provides a circuit to do the conversion. In practice, high-accuracy phase estimates necessitate that the switching of the output between high and low be very sharp. One way to obtain these sharp transitions is to have several stages of “amplify and clip” preceding the Schmitt trigger.
The digital portion of the zero-crossing device can be implemented with an edge-triggered RS flip-flop and some ancillary circuitry, while the low-pass filter on the output stage can be implemented with an RC network. A simple circuit to implement the digital part of the circuit is shown in Chapter 81.

A simpler method for measuring phase based on zero-crossings involves the use of an exclusive or (XOR) gate. Again, the analog input signals must first be converted to digital pulse trains. The two inputs are then fed into an XOR gate and finally into a low-pass averaging filter. The circuit is illustrated in Chapter 81. A disadvantage with this method is that it is only effective if the duty cycle is 50% and if the phase shift between the two signals is between 0 and π radians. It is therefore not widely used.

The Three-Voltmeter Method

The measurement of a phase difference between two voltage signals, $v_{ac}$ and $v_{bc}$, can be expedited if there is a common voltage point, $c$. The voltage between points $b$ and $a$ ($v_{ba}$), the voltage between points $b$ and $c$ ($v_{bc}$), and the voltage between points $c$ and $a$ ($v_{ca}$) are measured with three different voltmeters. A vector diagram is constructed with the three measured voltages as shown in Figure 41.9. The phase difference between the two vectors, $v_{ac}$ and $v_{bc}$, is determined using a vector diagram (Figure 41.9) and the cos rule. The formula for the phase difference, $\phi$, in radians is given by:

$$\pi - \phi = \cos^{-1} \left( \frac{v_{ca}^2 + v_{bc}^2 - v_{ba}^2}{2v_{ca}v_{bc}} \right)$$

**Figure 41.8** Input, output and intermediate signals obtained with the zero-crossing method for phase measurement. Note that the technique is not sensitive to signal amplitude.

The digital portion of the zero-crossing device can be implemented with an edge-triggered RS flip-flop and some ancillary circuitry, while the low-pass filter on the output stage can be implemented with an RC network. A simple circuit to implement the digital part of the circuit is shown in Chapter 81.

A simpler method for measuring phase based on zero-crossings involves the use of an exclusive or (XOR) gate. Again, the analog input signals must first be converted to digital pulse trains. The two inputs are then fed into an XOR gate and finally into a low-pass averaging filter. The circuit is illustrated in Chapter 81. A disadvantage with this method is that it is only effective if the duty cycle is 50% and if the phase shift between the two signals is between 0 and π radians. It is therefore not widely used.

The Three-Voltmeter Method

The measurement of a phase difference between two voltage signals, $v_{ac}$ and $v_{bc}$, can be expedited if there is a common voltage point, $c$. The voltage between points $b$ and $a$ ($v_{ba}$), the voltage between points $b$ and $c$ ($v_{bc}$), and the voltage between points $c$ and $a$ ($v_{ca}$) are measured with three different voltmeters. A vector diagram is constructed with the three measured voltages as shown in Figure 41.9. The phase difference between the two vectors, $v_{ac}$ and $v_{bc}$, is determined using a vector diagram (Figure 41.9) and the cos rule. The formula for the phase difference, $\phi$, in radians is given by:

$$\pi - \phi = \cos^{-1} \left( \frac{v_{ca}^2 + v_{bc}^2 - v_{ba}^2}{2v_{ca}v_{bc}} \right)$$

(41.10)
The Crossed-Coil Method

The crossed-coil phase meter is at the heart of many analog power factor meters. It has two crossed coils, denoted A and B, positioned on a common shaft but aligned at different angles (see Figure 41.10). The two coils move as one, and the angle between them, \( \beta \), never changes. There is another independent nonrotating coil, C, consisting of two separate parts, “enclosing” the rotating part (see Figure 41.10). The separation of coil C into two separate parts (forming a Helmholtz pair) allows the magnetic field of coil C to be almost constant in the region where the rotating A and B coils are positioned.

Typically the system current, \( I \), is fed into coil C, while the system voltage, \( V \), is applied to coil A via a resistive circuit. The current in coil A is therefore in phase with the system voltage, while the current in coil C is in phase with the system current. Coil B is driven by \( V \) via an inductive circuit, giving rise to a current that lags \( V \) (and therefore the current in coil A) by 90\(^\circ\). In practice, the angle between the currents in coils A and B is not quite 90\(^\circ\) because of the problems associated with achieving purely resistive and purely inductive circuits. Assume, then, that this angle is \( \beta \). If the angle between the currents in coil B and in coil C is \( \phi \), then the angle between the currents in coils A and C is \( \beta + \phi \). The average torque induced in coil A is proportional to the product of the average currents in coils A and C, and to the
cosine of the angle between coil A and the perpendicular to coil C. The average torque induced in coil A is therefore governed by the equation:

\[ T_A \propto I_A I_C \cos(\phi + \beta) \cos(\gamma) = k_A \cos(\phi + \beta) \cos(\gamma) \]  

(41.11)

where \( I_A \) and \( I_C \) = Constants
\( \omega = \) Angular frequency
\( \phi + \beta = \) Relative phase between the currents in coils A and C
\( \gamma = \) Angle between coil A and the perpendicular to coil C
\( \propto = \) Signifies “is proportional to”

Assuming that the current in coil B lags the current in coil A by \( \beta \), then the average torque in coil B will be described by:

\[ T_B \propto I_B I_C \cos(\phi) \cos(\gamma + \beta) = k_B \cos(\phi) \cos(\gamma + \beta) \]  

(41.12)

where \( I_B \) is a constant, \( \phi \) is the relative phase between the currents in coils B and C, and the other quantities are as in Equation 41.11.

Now, the torques due to the currents in coils A and B are designed to be in opposite directions. The shaft will therefore rotate until the two torques are equal; that is, until:

\[ k_A \cos(\phi + \beta) \cos(\gamma) = k_B \cos(\phi) \cos(\gamma + \beta) \]  

(41.13)

If \( k_A = k_B \), then Equation 41.13 will be satisfied when \( \phi = \gamma \). Thus, the A coil will be aligned in the direction of the phase shift between the load current and load voltage (apart from errors due to the circuits of the crossed coils not being perfectly resistive/inductive). Thus, a meter pointer attached to the A plane will indicate the angle between load current and voltage. In practice, the meter is usually calibrated to read the cosine of the phase angle rather than the phase angle, and also to allow for the errors that arise from circuit component imperfections.

The accuracy of this method is limited, due to the heavy use of moving parts and analog circuits. Typically, the measurement can only be made accurate to within about \( 1^\circ \).

**Synchroscopes and Phasing Lamps**

The crossed-coil meter described above is used as the basis for synchroscopes. These devices are often used in power generation systems to determine whether two generators are phase and frequency synchronized before connecting them together. In synchroscopes, the current from one generator is fed into the fixed coil and the current from the other generator is fed into the movable crossed coils. If the two generators are synchronized in frequency, then the meter needle will move to the position corresponding to the phase angle between the two generators. If the generators are not frequency synchronized, the meter needle will rotate at a rate equal to the difference between the two generator frequencies. The direction of rotation will indicate which generator is rotating faster.

When frequency synchronization occurs (i.e., the meter needle rotation ceases) and the phase difference is zero, the generators can be connected together. Often in practice, the generators are connected before synchronization occurs; the generator coming on-line is deliberately made a little higher in frequency so that it can provide extra power rather than be an extra drain on the system. The connection is still made, however, when the instantaneous phase difference is zero.

*Phasing lamps* are sometimes used as a simpler alternative to synchroscopes. A lamp is connected between the two generators, and any lack of frequency synchronization manifests as a flickering of the lamp. A zero phase difference between the two generators corresponds to maximum brightness in the lamp.
Alternating voltages (and currents) are often characterized as vectors consisting of a magnitude and a phase, with the phase being measured relative to some desired reference. Many instruments exist that can display the voltage amplitude and phase of a signal across a wide range of frequencies. These instruments are known as vector voltmeters or network analyzers. The phase and amplitude as a function of frequency can be obtained very simply in principle by taking the Fourier transform of the signal and simply reading the amplitude and phase across the continuum of frequencies. To achieve good accuracy, this is typically done with down-conversion and digital processing in the baseband region. The down-conversion can be analog, or it can be digital. The procedure is described more fully in the succeeding paragraphs.

To determine the real part of the voltage vector at a given frequency $f$, the signal is first down-converted by mixing with a local oscillator signal, $\cos(2\pi ft)$. This mixing of the signal recenters the frequency component of interest at 0 Hz. The resultant signal is low-pass filtered, digitally sampled (if not in the digital domain already), and averaged. The digital sampling and averaging enables the amplitude of the newly formed 0-Hz component to be evaluated. The imaginary part is obtained in similar fashion by mixing the signal with $\sin(2\pi ft)$, low-pass filtering, digitally sampling, and again averaging the samples. The amplitude and phase of the voltage vector, $V$, are obtained from the real and imaginary parts using the standard trigonometric relationships:

\[
\text{Magnitude} = |V| = \sqrt{\Re\{V\}^2 + \Im\{V\}^2}
\]

\[
\text{Phase} = \arg(V) = \arctan\left(\frac{\Im\{V\}}{\Re\{V\}}\right)
\]  

where $\Re\{\cdot\}$ and $\Im\{\cdot\}$ denote the real and imaginary parts, respectively.

The procedure for forming the vector voltage is summarized in the block diagram in Figure 41.11. In practice, the down-conversion can be carried out in more than one step. For high-frequency signals, for example, the first stage might shift a large band of frequencies to the audio region, where further down-conversion is carried out. Alternatively, the first stage might shift a band of frequencies to the intermediate frequency (IF) band, and the second stage to the audio band. More details on the physics of the down-conversion process are available in the article on “Modulation” in Chapter 81.
Just as it is possible to analyze a voltage signal and produce a magnitude and phase across any given frequency band, so it is possible to obtain a frequency profile of the magnitude and phase of a current signal. If current vectors and voltage vectors can be obtained for a given impedance, then it is possible to obtain a “vector impedance.” This impedance is defined simply as the result of the complex division of voltage by current:

\[ Z = \frac{V}{I} \]  

(41.16)

The calculation of vector impedances are useful for such applications as impedance matching, power factor correction, and equalization.

Typically, much of the current processing for vector voltmeters and vector impedance meters is done digitally. One of the great advantages of this type of processing is the high accuracy achievable. Accuracies of 0.02° are common, but this figure is improving with developing technology. The high sampling rates that can be employed (typically beyond 1 GHz) cause the errors in the A/D conversion to be spread out over very large bandwidths. Since the ultimate measurement of a vector voltage or impedance is usually made over a very narrow bandwidth, the errors are substantially eliminated. The developments in technology that enable greater accuracy are (1) sampling rate increases, (2) word-length increases, and (3) increased A/D converter fidelity.

**Phase Standard Instruments**

For high-precision phase measurements and calibration, “phase standard” instruments can be used. These instruments provide two sinusoidal signal outputs, whose phase difference can be controlled with great accuracy. They typically use crystal-controlled timing to digitally synthesize two independent sinusoids with a variable user-defined phase difference. The Clarke-Hess 5500 Digital Phase Standard is one such instrument. For this standard, the sinusoids can have frequencies ranging from 1 Hz to 100 kHz, while amplitudes can vary between 50 mV and 120 V rms. The phase can be set with a resolution of 0.001°, with a typical accuracy of about 0.003°.

**The Fast Fourier Transform Method**

This method is one in which virtually all the processing is done in the digital domain. It operates on the pulse code modulated (PCM) digital samples of a signal. This and other similar methods are very promising means for measuring phase. This is because of the digital revolution that has resulted in cheap, fast, accurate, and highly versatile digital signal processors (DSPs). The latter are small computer chips capable of performing fast additions and multiplications, and which can be programmed to emulate conventional electronic functions such as filtering, coding, modulation, etc. They can also be programmed to perform a wide variety of functions not possible with analog circuitry. Up until the end of the 1980s, digital measurement was limited by the relatively inaccurate analog-to-digital (A/D) conversion process required before digital processing could be performed. Developments in the early 1990s, however, saw the introduction of oversampling analog-to-digital converters (ADCs), which can achieve accuracies of about one part in 100,000 [3]. ADC speeds as well as DSP chips are now running reliably at very high speeds.

In the fast Fourier transform (FFT) method, the digital signal samples are Fourier transformed with an FFT [2]. If the signal is sinusoidal, the initial phase is estimated as that value of the phase where the Fourier transform is maximized [4]. The frequency of the signal is estimated as that value of frequency where the Fourier transform is maximized. Once measurements of the frequency \( f \) and initial phase \( \phi_0 \) have been obtained, the phase at any point in time can be calculated according to:

\[ \phi = 2\pi ft + \phi_0 \]  

(41.17)
One important practical issue in the measurement of the frequency and initial phase with an FFT arises because the FFT yields only samples of the Fourier transform; that is, it does not yield a continuous Fourier transform. It is quite possible that the true maximum of the Fourier transform will fall between samples of the FFT. For accurate measurement of frequency and initial phase, then, it is necessary to interpolate between the FFT samples. An efficient algorithm to do this is described in [5].

The FFT method is particularly appealing where there is significant noise present, as it is effective down to quite low signal-to-noise ratios (SNRs). Furthermore, it provides an optimal estimate of the frequency and initial phase, providing the background noise is white and Gaussian, and that no harmonic components are present [4]. If harmonics are present, the estimate of the phase is commonly taken as the phase at the FFT peak corresponding to the fundamental; this is not an optimal estimate, but serves well in many applications. An optimal estimate in the case when harmonics are present can be obtained, if necessary, with the algorithms in [6], [7], and [8]. DSP chips such as the Texas Instruments TMS320C3x family, the Analog Devices ADSP21020 chip, or the Motorola MC5630x series can be used to implement the real-time FFTs.

If long word-lengths are used (say 32 bits) to perform the arithmetic for the FFTs, then determination of the phase from the samples of the FFT is virtually error-free. The only significant inaccuracy incurred in determining the phase is due to the ADC errors. Moreover, the error due to the digitization will typically be spread out over a large bandwidth, only a small amount of which will be “seen” in the phase measurement. With a high-quality ADC, accuracies of less than 0.001° are possible.

Phase-Locked Loops

If the frequency of a signal changes significantly over the period of the measurement, the FFT method described above will provide inaccurate results. If the signal’s frequency does change substantially during measurement, one means to estimate the phase of the signal is to use a phase-locked loop (PLL). In this case, the signal, \( s(t) = A \sin(\omega t + \phi(t)) \), can be thought of as a constant frequency component, \( A \sin(\omega t) \), which is phase modulated by a time-varying phase component, \( \phi(t) \). The problem then reduces largely to one of demodulating a phase-modulated (PM) signal. A PLL can be used to form an estimate of the “phase-modulating” component, \( \hat{\phi}(t) \), and the overall phase of the signal, \( \phi_{oa} \), can be estimated according to:

\[
\phi_{oa}(t) = \omega t + \hat{\phi}(t)
\]  

Either analog or digital PLLs can be used, although higher accuracy is attainable with digital PLLs. Analog PLLs for demodulating a frequency-modulated (FM) signal are discussed in Chapter 81 and in [12]. The digital PLL (DPLL) was developed as an extension of the conventional analog PLL and is therefore similar in structure to its analog counterpart. The DPLL is discussed in [9] and [10]. The equation to demodulate the digital modulated signal with a first order DPLL is a simple recursive equation [9].

A block diagram of the DPLL for demodulating a PM signal is shown in Figure 41.12. In this diagram, \( n \) represents the discrete-time equivalent of continuous time. It can be seen that there are strong similarities between Figure 41.12 and the analog PLL-based FM demodulator in Chapter 81. Both have phase comparators (implemented by the multiplier in Figure 41.12), both have loop filters, and both have modulators (either PM or FM) in the feedback loop.

The DPLL can easily be extended to measure the phase of a signal consisting not just of a fundamental component, but also of harmonically related components. Details are provided in [11]. The DPLL is near optimal for phase estimation in white Gaussian background noise down to a signal power-to-noise power ratio of about 8 dB [10].

The DPLL will function effectively whether the phase is constant or time-varying. Unlike the FFT, the DPLL is a recursive algorithm, with the feedback involved in the recursion creating a vulnerability to quantization errors. However, with proper precautions and long word-lengths, the DPLL will introduce
It is frequently necessary to track the phase of a carrier that "jitters" in some uncertain manner. This tracking of the carrier phase is necessary for synchronous demodulation schemes, where the phase of the demodulating signal must be made equal to the phase of the carrier. This need is explained in Chapter 81, and is briefly re-explained here. Consider, for example, double sideband (DSB) amplitude modulation. In DSB, the modulated signal is given by:

$$f_s(t) = A[k + \mu m(t)] \cos(\omega_c t)$$

where $m(t)$ is the message signal, $A$ is the amplitude of the unmodulated carrier, $\mu$ is the modulation index, $k$ is the proportion of modulating signal present in the modulated signal, and $\cos(\omega_c t)$ is the carrier. Demodulation is typically carried out by multiplying $f_s(t)$ by the carrier, and then low-pass filtering so that the demodulated signal is given by:

$$f_d(t) = \frac{A[k + \mu m(t)]}{2}$$

However, if because of carrier uncertainty, one multiplies the modulated signal by $\cos(\omega_c t + \phi)$, then the demodulated signal is given by:

$$f_d(t) = \frac{A[k + \mu m(t)] \cos(\phi)}{2}$$

It can be seen from Equation 41.20 that the error in the carrier phase can affect both the amplitude and the sign of the demodulated signal. The phase errors can thus yield substantial errors in system output. The following sections outline important techniques used for tracking the phase of carriers, and thus reducing phase errors.

The Phase-Locked Loop for Carrier Phase Tracking

The phase-locked loop (PLL) is well known as a means for demodulating frequency-modulated signals. It is also frequently used for tracking the phase of a carrier in noise, so that a copy of the carrier with correct phase is available for demodulation. This tracking is simple enough if a (noisy) copy of the carrier is directly available; either a digital or analog PLL can be used. In either case, the input can be assumed to have the form, $A \sin(\omega t + \phi(t))$, where $\phi(t)$ is the carrier phase. The PLL consists of a multiplier (effectively a phase comparator), a phase modulator, and a loop filter, arranged as shown in Chapter 81. The design of the loop filter is critical if noise is to be optimally removed. In proper
operation, the PLL output will track the phase of the incoming signal (i.e., of the carrier). If a copy of the carrier is not available but needs to be inferred from the modulated signal, the demodulation task is more difficult. Digital PLLs using a DSP chip can be particularly helpful in this case; the carrier can be adaptively estimated using intelligent algorithms, with convergence to the “correct” signal being registered when certain desired features of the demodulated signal are observed.

The PLL is quite versatile. It can function in relatively low noise environments (typically down to about 8 dB SNR). It can be implemented digitally. It can also cope with substantial carrier frequency variations by increasing the order of the loop filter [12]; (this is often necessary, for example, in satellite communications because of the Doppler effect). At very low SNR, however, the PLL fails badly. Recent developments in digital signal processing have seen the development of an alternative based on hidden Markov models (HMMs), which will function down to about –5 dB SNR [13]. The HMM method is discussed in the next section.

**Hidden Markov Model-Based Carrier Phase Tracker**

In the HMM method, the problem of estimating the phase and frequency of a noisy waveform is couched as a “state estimation” problem. The phase of the signal at any point in time can go from 0 to 360°. The 0 to 360° value range is divided into a finite number of intervals or “states,” so that the phase at any time occupies a particular (though unknown) state. Similarly, the angular frequency normalized by the sampling frequency at any time in a digital system must be between –π to +π. This value range is also divided into a number of states, so that the frequency at any time has a (hidden or unknown) state associated with it. The frequency is assumed to be a first-order Markov process and probabilities are assigned to the possibility of the frequency changing from one state to another for successive values of time, i.e., frequency transition probabilities are assigned. Large frequency changes are assigned low probabilities, while small changes are assigned high probabilities. The problem of estimating the true phase and frequency states underlying the noisy signal then reduces to one of estimating which states the phase and frequency occupy as time evolves, given the observed noisy signal and the transition probabilities. Computationally efficient optimal algorithms have been developed to estimate these “optimal state sequences” for both the phase and frequency. Details are provided in [13].

### 41.5 Power Factor

Of particular interest in many applications is the phase angle between the current and voltage of a system. This angle is important because it is a measure of the power which is dissipated in the system. The following paragraphs discuss this angle, its cosine (the system power factor), and its measurement.

In a linear electric circuit that is fed by a current of peak amplitude, $I_m$, with an angular frequency of $\omega$, the current will have the form, $I_m \cos(\omega t)$. The system voltage will be given by $V_m \cos(\omega t + \phi)$, where $V_m$ is the peak voltage and $\phi$ is the phase difference between the current and voltage. Then the average power dissipated in the circuit will be given by:

$$P_\text{av} = \frac{1}{2} V_m I_m \cos(\phi) = V_{\text{rms}} I_{\text{rms}} \cos(\phi)$$  \hspace{1cm} (41.21)

where $V_{\text{rms}}$ and $I_{\text{rms}}$ are the root mean square (rms) values of the voltage and current respectively. The term $\cos(\phi)$ is known as the power factor. It may alternatively be expressed as the ratio of real average power to the product of the rms values of voltage and current, respectively:

$$PF = \frac{P_\text{av}}{V_{\text{rms}} I_{\text{rms}}}$$  \hspace{1cm} (41.22)
The above expression is, in fact, a general definition of power factor for any current and voltage waveforms. For the special case of sinusoidal voltage and currents, \( PF \) reduces to \( \cos(\phi) \).

There are a number of ways to measure the power factor. One way is to use a wattmeter to measure the real average power and a voltmeter and an ammeter to measure the rms voltage and current, respectively. The power factor is then determined according to Equation 41.22. This is probably the most effective way when the currents and/or voltages are nonsinusoidal. This procedure can easily be implemented with “digital power meters.” The power is measured by time-averaging the product of the instantaneous voltage and current, while the rms values are calculated by taking the square root of the time averaged value of the square of the parameter of interest — current or voltage. Some digital power meters also provide an analysis of the individual harmonics via FFT processing. These meters are accurate and versatile, and consequently very popular.

A more direct method is based on the crossed-coil meter, the operation of which was described earlier in this chapter. Note that this meter is a “single-phase meter,” which is accurately designed for one frequency only. Errors will occur at other frequencies because of the dependance of the crossed-coil meter method on a constant and known phase angle between the currents in the crossed coils.

With balanced polyphase circuits, it is possible to use a single-phase meter applied to one of the phases. Alternatively, one can use specially designed polyphase meters. In a three-phase meter, for example, one phase is connected to the fixed coil, while the other two phases are connected to the crossed coils on the rotating shaft. The crossed coils are constructed with a \( 60^\circ \) angle between them. With four-phase systems, consecutive lines are \( 90^\circ \) out of phase. Two of these consecutive lines are connected to the two crossed-coils and the angle between the coils is made equal to \( 90^\circ \).

With unbalanced polyphase circuits amidst the presence of harmonics, each of the harmonic components has its own power factor, and so it is likely to be misleading to use a meter that measures a single angle. These methods based on the crossed-coil meter are thus much more limited than their digital counterparts.

### 41.6 Instrumentation and Components

Table 41.1 lists some integrated circuits and DSP chips that can be used in the various techniques for measuring phase. The list is really only illustrative of what is available and prices are approximate costs in U.S. dollars for small quantities at the end of 1996. Table 41.2 lists some companies that manufacture these products. An extensive (and indeed rapidly increasing) product range exists for DSP chip-based products, with details being available from the companies listed in Table 41.2. Table 41.3 lists instruments used for phase measurement. These instruments include CROs, vector voltage meters, vector impedance meters, crossed-coil meters and digital power meters, zero-crossing meters, and phase standards. Again, the table is only representative, as the full range of available instruments is enormous. Addresses of some of the relevant companies are provided in Table 41.4.

42.4 Accuracy of Energy Meters

Energy is one of the most important physical quantities in any branch of science and engineering and especially in electrical engineering. Energy exchange processes lead to the study of electric networks from the physical point of view and allow an in-depth knowledge of power transfer within the electrical world and between electric and other forms of energy.

The definitions of energy and power represent the starting point for any successive study.

1. Energy is the amount of work that the system is capable of doing.
2. Power is the time rate of doing work.

Energy can be mathematically defined as the definite integral of the power over a given time interval $\Delta t$.

The power available in a two-terminal section of an electric circuit is given by the product of the voltage across the terminals and the current flowing through the section itself ($p = vi$). The electric energy ($E$) flowing through the same section is defined by the integral of the power over the observation interval:

$$E(\Delta t) = \int_{t_0}^{\Delta t + t_0} p\,dt$$  \hspace{1cm} (42.1)

For this reason, energy measurement is a dynamic measurement, which means it varies with time. The energy measurement unit is the Joule (J); but for the electric energy, the Watthour (Wh) is most common.

The electrostatic energy is defined as the product of the electric charge and the difference of electric potential.

Electricity is generated from different forms of energy (thermal, hydraulic, nuclear, chemical, etc.); after electric transfer and distribution processes, it is converted to other forms of energy. The main feature of electric energy is the simplicity by which one can transfer it over long distances, control the distribution, and measure energy consumption.
42.1 Dc Energy Measurement

The simplest way to perform this measurement is to measure voltage and current and then compute the product:

\[ E = V I \Delta t \]  

(42.2)

where \( \Delta t \) is the observation interval measured by means of a chronometer or a time counter.

Note that dc systems are limited to a restricted number of applications in power systems, as, for example: electric traction, electric drives, electrochemical power plants, and for HVDC transmission system in limited operating conditions. All these cases, nevertheless, allow energy measurement either on the dc or ac side of the network.

The dc energy measurement has been performed in the past by means of different methodologies and instruments such as electrodynamic measurement devices (Electrodynamics dc Energy Meter) operating as an integrating wattmeter (Figure 42.1). This measuring instrument is built using a small dc motor without iron, whose magnetic field is generated by the line current flowing through a coil arranged as the fixed part of the system. The rotor is connected in series with an additional resistor and is powered by the line voltage \( (V) \). Because of the lack of the iron in the magnetic circuit, the rotor magnetic flux \( \phi \) is strictly proportional to the current \( I \).

The rotor current (derived from the line voltage) is:

\[ I_v = \frac{(V - E)}{R} \]  

(42.3)

where \( E = k \Gamma \phi \) is the emf induced by the angular speed \( \Gamma \), and \( R \) is the total resistance of the voltage circuit. It is possible to make the emf \( E \) negligible because of low angular speed \( \Gamma \), limited amplitude of the flux \( \phi \), and a significant resistance \( R \). In this way, Equation 42.3 becomes:

\[ I_v = \frac{V}{R} \]  

(42.4)

The torque \( C_m \) provided by the motor can be written:

\[ C_m = k_2 \phi I_v = k_1 IV/R = k_4 P \]  

(42.5)
$C_m$ is therefore approximately proportional to the power $P$ flowing through the line. It is necessary, however, to remember that this torque could create a high angular speed to the rotor, because of constantly incrementing speed. In order to maintain dynamic equilibrium, a simple aluminum disk mounted on the rotor axis and placed in a constant magnetic field provided by a permanent magnet $M$, is added to the dc motor system. In this way, the induced currents in the disk introduce a damped torque proportional to the angular speed $\Gamma$, so, at equilibrium, there is a linear dependence of $\Gamma$ on the power $P$. Thus,

$$E = \int_{\Delta t} P \, dt = k \int_{\Delta t} \Gamma \, dt$$  \hspace{1cm} (42.6)$$

A mechanical counter transfers the rotating motion into a digital representation of the total energy consumed during a specific time interval $\Delta t$ in the power system.

### 42.2 ac Induction Energy Meters

The most traditional and widely used ac energy meter is the induction meter. This device is built by means of three electric circuits, magnetically coupled, two of them fixed and one rotating around the mechanical axis of the system. Figure 42.2 shows the two fixed circuits, (1) and (2), which are the voltage and the current coils. The third circuit is the rotating disk (3), generally made of aluminum, mounted on a rigid axis (4) transmitting the disk rotation to a mechanical counter (6), which provides the energy display.

The fixed circuits (1) and (2) provide magnetic fluxes interacting with the rotating disk. Fixed circuits (1) and (2) form a C shape and the disk is placed in their iron gaps. Another similar structure, arranged using a permanent magnet (5), is placed over the disk as well. The magnetic fluxes generated by the voltage and current circuits are at the same frequency and are sinusoidal. They induce currents in the rotating disk that, by means of a cross-interaction with the two generating fluxes, provide a mechanical torque acting on the disk. The torque is given by:

$$C_m = K VI \sin(\alpha)$$  \hspace{1cm} (42.7)$$

where $C_m = \text{Mechanical torque}$

- $K = \text{System constant}$
- $V = \text{rms of the value of the applied voltage}$
- $I = \text{rms of the value of the applied current}$
- $\alpha = \text{Phase angle between the fluxes generated by } V \text{ and } I$

The acting torque causes the disk to rotate around its axis. This rotation reaches a dynamic equilibrium by balancing the torque $C_m$ of the voltage and current coils and the reacting torque generated by permanent magnet. The resulting angular speed, $\Gamma$, is therefore proportional to the flowing power if:

- The angular speed $\Gamma$ of the disk is much smaller than the voltage and current frequency $\omega$
- The phase difference between the voltage and current fluxes is equal to $\alpha = \pi - \varphi$, where $\varphi$ is the phase difference between the voltage and current signals

The angular speed of the rotating disk can be written as:

$$\Gamma = \left(1/k\right) \omega \left( R_2/Z_2^2 \right) \left( M_1 I \right) \left( M_2 V/Z_2 \right) \cos(\phi) = KP$$  \hspace{1cm} (42.8)$$

where $\Gamma = \text{Angular speed of the rotating circuit (conductor disk), in rad s}^{-1}$

- $K = \text{Instrument constant, in rad s}^{-1} \text{ W}^{-1}$
- $P = \text{Mean power in the circuit, in W}$
- $1/k = \text{Constant, in } \Omega \text{ V}^{-2} \text{ s}^{-2}$
\[ \omega \] = Voltage and current frequency, in rad s\(^{-1}\)

\[ R_e \] = Equivalent resistance of the rotating disk, relative to the induced current fields, in \( \Omega \)

\[ Z_z \] = Equivalent impedance of the rotating disk, relative to the induced current fields, in \( \Omega \)

\[ (M_2 V/Z_z) \] = rms value of the common flux related to the circuits n. 1 and 3, in Wb

\[ (M_1 I) \] = rms value of the common flux related to the circuits n. 2 and 3, in Wb

\[ Z_2 \] = Impedance of the voltage circuit (n. 1), in \( \Omega \)

\[ V \] = rms value of the applied voltage, in V

\[ I \] = rms value of the applied current, in A

\[ \phi \] = Phase difference between current and voltage signals
The integral of $\Gamma$ over a defined period $\Delta t$ is proportional (with enough accuracy) to the energy flowing in the power circuit. Thus, it is true that the instrument constant $K$ is strictly related (but not proportional) to the signal frequency $\omega$.

### 42.3 Static Energy Meters

The development of electronic multipliers led to their use in energy meters that directly multiply voltage by current. In their first version, electronic multipliers used analog components (operational amplifiers, resistors, capacitors, etc.), while recent devices use digital components and programmable logic systems. Voltage and current signals are processed to obtain a signal proportional to the real power flowing into the line. The result is integrated over the observation time in order to calculate the measured energy. The devices based on these components are completely static (i.e., they do not have any moving parts). Moreover, because these electronic components have a frequency range from dc to high frequencies, instruments based on them can be applied to dc, ac, or distorted power systems (some care must be taken in order to provide a correct sampling of signals in all-digital systems).

There are many different prototypes in this class of energy meters. The first realizations were based on analog multipliers and, even if they were not able to replace the traditional induction energy meters, they represented a good solution for all those applications where an increased accuracy was required (up to 0.2%). Now, more sophisticated digital instruments are under design and development, based on dedicated structures mainly implementing DSPs (digital signal processors) as powerful tools for numerical computation and sigma-delta analog-to-digital converters (ADCs) in order to optimize the conversion process.

Many of these instruments can be analyzed by means of the following functional descriptions.

#### The Electronic Energy Meter

Figure 42.3 shows the block diagram of an electronic energy meter. The main feature of this type of instrument is the presence of voltage inputs on both voltage and current channels, because the electronic circuitry accepts only voltage signals. It has negligible current consumption from the system under measurement, due to high input impedance. Moreover, the maximum amplitude level of the input signal must be limited to around 5 V to 15 V. For this reason, the conditioning apparatus must guarantee the correct current-to-voltage transformation and the proper voltage reduction. This type of instrument can work at dc (which omits voltage and current transformers) or ac power systems and can also measure energy from distorted signals.

#### The Conditioning System for dc Electronic Energy Meters

The basic blocks of the conditioning system for a dc energy meter are formed from a voltage divider for the voltage input, and a shunt for the current input. After these passive components, two preamplifiers are usually introduced before the processing system. The current preamplifier is very important because:

1. The voltage output level of the current shunt is very low, even at full scale ($\leq 1$ V).
2. Many times, the current input has to support overloaded signals; the presence of a variable gain amplifier allows acceptable working conditions for the system.
3. It can be used to implement an active filter before signal processing.

#### Voltage and Current Adapters for ac Electronic Energy Meters

The most common devices to process ac signals for static energy meters are the traditional voltage and current transformers. They must be made with proper components to achieve the right amplitude of the voltage inputs (by nonreactive shunts for the current transformers, and nonreactive voltage dividers for
the voltage transformers). After the transformers, and related devices, a second block, based on electronic amplifiers, provides the final analog processing of the input signals, as for the dc conditioning systems. It is useful to introduce this second processing element because analog filters are generally required when the input signals need to be digitally processed.

### Electronic-Analog Energy Meters with Digital Output

These instruments provide the product of the two input signals (both voltages) through an analog multiplier that evaluates a voltage output proportional to the power of the input signals. This output can be followed by a filtering block.

The output signal is proportional to the instantaneous electric power flowing through the line. To calculate the energy, it is now necessary to complete the process by integrating over the observation time. This last procedure can be performed in two different ways.

**1st procedure:** The power signal at the output of the analog multiplier is applied to the input of a voltage frequency converter. Thus, the power information is converted from a voltage level to the frequency pulse sequence, for which the counting process performs the integration of the power in the observation interval, i.e., the measurement of energy.

The final measurement can be performed by means of an electronic counter with digital display or using a dc step motor incrementing the rotor angular position every pulse by a fixed angular increment. The rotor position is shown by a mechanical counter (similar to the system mounted on the induction energy meters) indicating the total number of complete rotations performed by the system, proportional to the energy of the system under measurement. This second arrangement is normally adopted because it allows a permanent record of the energy information, which is not subject to possible lack of electric energy as in the first case.

**2nd procedure:** This arrangement is based on an analog-to-digital converter (ADC) connected to the output of the analog multiplier. The sampling process is driven by an internal clock. Thus, the ADC
provides uniform sampling over the signal period and, under the condition imposed by the sampling theorem, the sum of the samples is proportional to the integral of the power signal, i.e., to the energy during the observation interval.

The calculation is performed by means of a dedicated CPU and then the results are sent to the digital memory to be stored and displayed. They can also be used to manage any other automatic processes based on the energy measurement. For this purpose, data are available on a data bus (serial or parallel) connecting the measuring system with other devices.

The sampling process is performed by a Sample & Hold circuit.

All-Digital Energy Meters

The most advanced solution for energy measurement can be found in all-digital meters (Figure 42.4), where both the voltage and current signals are sampled before any other processing. Thus, the data bus presents the sampled waveforms in digital form, giving the opportunity to perform a wide choice of digital signal processing on the power and energy information. Both sampling devices are driven by a CPU, providing synchronized sampling signals.

Sometimes, the system is equipped with a DSP capable of providing hardware resources to implement real-time evaluation of complex parameters (i.e., signal transforms) of the signal and energy measurement. Dedicated hardware and software performing instrument testing are also integrated into the meter to complete the device with the most advanced features.

Filters able to meet the sampling theorem requirements, programmable gain amplifiers, and Sample & Hold circuits generally precede the ADCs.

Data management is arranged in two possible ways: sending the sampled data directly to the processing system for calculations, or accessing the memory using DMA procedures, so the data string for a specific time period is first stored and then used for computation of energy and related parameter values. Final results of this computation are then available on the system bus to be sent to the other system resources or to be displayed.
Accuracy of energy meters is defined by means of relative parameters (in percent) obtained from a testing process by powering the instrument with a constant (nominal) voltage signal and a variable current signal (5, 10, 20, 50, 100, 120% of the nominal value). The testing procedures are performed by comparing the meter under test with a standard meter (Figure 42.5), or using equivalent methods.

The accuracy of commercial electromechanical (induction) energy meters is generally around 2%. Energy meters with accuracies of 1% have also been built. Electronic energy meters have a better accuracy, generally between 0.5% and 0.2%.

Further Information

Electrical Conductivity and Resistivity

43.1 Basic Concepts

The electrical resistivity of a material is a number describing how much that material resists the flow of electricity. Resistivity is measured in units of ohm-meters ($\Omega \cdot m$). If electricity can flow easily through a material, that material has low resistivity. If electricity has great difficulty flowing through a material, that material has high resistivity. The electrical wires in overhead power lines and buildings are made of copper or aluminum. This is because copper and aluminum are materials with very low resistivities (about 20 n$\Omega \cdot m$), allowing electrical power to flow very easily. If these wires were made of high resistivity material like some types of plastic (which can have resistivities about 1 E$\Omega \cdot m$ ($1 \times 10^{18} \Omega \cdot m$)), very little electric power would flow.

Electrical resistivity is represented by the Greek letter $\rho$. Electrical conductivity is represented by the Greek letter $\sigma$, and is defined as the inverse of the resistivity. This means a high resistivity is the same as a low conductivity, and a low resistivity is the same as a high conductivity:

$$\sigma \equiv \frac{1}{\rho} \quad (43.1)$$
This chapter will discuss everything in terms of resistivity, with the understanding that conductivity can be obtained by taking the inverse of resistivity. The electrical resistivity of a material is an intrinsic physical property, independent of the particular size or shape of the sample. This means a thin copper wire in a computer has the same resistivity as the Statue of Liberty, which is also made of copper.

**43.2 Simple Model and Theory**

Figure 43.1 shows a simple microscopic model of electricity flowing through a material [1]. While this model is an oversimplification and incorrect in several ways, it is still a very useful conceptual model for understanding resistivity and making rough estimates of some physical properties. A more correct understanding of the electrical resistivity of materials requires a thorough understanding of quantum mechanics [2].

On a microscopic level, electricity is simply the movement of electrons through a material. The smaller white circle in Figure 43.1 represents one electron flowing through the material. For ease of explanation, only one electron is shown. There are usually many electrons flowing through the material simultaneously. The electron tends to move from the left side of the material to the right side because an external force (represented by the large minus and plus signs) acts on it. This external force could be due to the voltage produced by an electrical power plant, or a battery connected to the material. As the electron moves through the material, it collides with the “stationary” atoms of the material, represented by the larger black circles. These collisions tend to slow down the electron. This is analogous to a pinball machine. The electron is like the metal ball rolling from the top to the bottom of a pinball machine, pulled by the force of gravity. The metal ball occasionally hits the pins and slows down. Just like in different pinball machines, the number of collisions the electron has can be very different in different materials. A material that produces lots of collisions is a high-resistivity material. A material that produces few collisions is a low-resistivity material.

The resistivity of a material can vary greatly at different temperatures. The resistivity of metals usually increases as temperature increases, while the resistivity of semiconductors usually decreases as temperature increases. The resistivity of a material can also depend on the applied magnetic field.

The discussion thus far has assumed that the material being measured is homogeneous and isotropic. Homogeneous means the material properties are the same everywhere in the sample. Isotropic means the material properties are the same in all directions. This is not always a valid assumption. A more exact definition of resistivity is the proportionality coefficient \( \rho \) relating a local applied electric field to the resultant current density:

\[
E \equiv \rho J
\]

where \( E \) is the electric field (V/m), \( J \) is the current density (A m\(^{-2}\)), and \( \rho \) is a proportionality coefficient (Ω m). Equation 43.2 is one form of Ohm’s law. Note that \( E \) and \( J \) are vectors, and \( \rho \) is, in general, a...
This implies that the current does not necessarily flow in the direction of the applied electric field. In this chapter, isotropic and homogeneous materials are assumed, so $\rho$ is a scalar (a single number).

Now consider the bar-shaped sample shown in Figure 43.2. The electric field $E$ is given by the voltage $V$ divided by the distance $l$ over which the voltage is applied:

$$ E \equiv \frac{V}{l} \quad (43.3) $$

The current density $J$ is given by the current $I$, divided by the cross-sectional area $A$ through which the current flows:

$$ J \equiv \frac{I}{A} \quad (43.4) $$

where the area $A$ in Figure 43.2 is equal to the width $w$ times the height $h$. Combining Equations 43.2, 43.3, and 43.4 and rearranging gives:

$$ V = \frac{I\rho l}{A} \quad (43.5) $$

Now define a new quantity called "resistance" $R$ with the definition:

$$ R \equiv \frac{\rho l}{A} \quad (43.6) $$

Combining Equations 43.5 and 43.6 then gives:

$$ I = \frac{V}{R} \quad (43.7) $$

where $I$ is the current in amps (A) flowing through the sample, $V$ is the voltage in volts (V) applied across the sample, and $R$ is the resistance in ohms (Ω) of the sample. Equation 43.7 is another form of Ohm's law.

Note that the resistance $R$ can depend on the size and shape of the sample, while $\rho$ is independent of the size or shape of the sample. For example, if the length $l$ of the sample bar is doubled, the resistance will double but the resistivity will remain constant.
The quantitative relationship between the resistivity $\rho$ and the simple microscopic model shown in Figure 43.1 is given by:

$$\rho = \frac{m}{ne^2 \tau}$$  \hspace{1cm} (43.8)

where $m$ is the mass of an electron, $n$ is the number of electrons per unit volume carrying current in the material, $e$ is the electric charge on an electron, and $\tau$ is the average time between collisions of an electron with the stationary atoms of the material. If there were more electrons per unit volume, they could carry more current through the material. This would lower the resistivity. If the electric charge on the electrons were greater, then the applied voltage would pull harder on the electrons, speeding them up. This would lower the resistivity. If the average time between collisions with the stationary atoms were longer, then the electrons could get through the material quicker. This would lower the resistivity. If electrons could be made more massive, they would move slower and take longer to get through the material. This would increase the resistivity.

### 43.3 Experimental Techniques for Measuring Resistivity

#### Two-Point Technique

The resistivity of a material can be obtained by measuring the resistance and physical dimensions of a bar of material, as shown in Figure 43.2. In this case, the material is cut into the shape of a rectangular bar of length $l$, height $h$, and width $w$. Copper wires are attached to both ends of the bar. This is called the two-point technique, since wires are attached to the material at two points. A voltage source applies a voltage $V$ across the bar, causing a current $I$ to flow through the bar. (Alternatively, a current source could force current through the sample bar, while a voltmeter in parallel with the current source measures the voltage induced across the sample bar.) The amount of current $I$ that flows through the bar is measured by the ammeter, which is connected in series with the bar and voltage source. The voltage drop across the ammeter should be negligible. The resistance $R$ of the bar is given by Equation 43.8a:

$$R = \frac{V}{I}$$  \hspace{1cm} (43.8a)

where $R =$ Resistance in $\Omega$

$V =$ Voltage in volts

$I =$ Current in amps

The physical dimensions can be measured with a ruler, a micrometer, or other appropriate instrument. Consult earlier sections of this Handbook for guidance on measuring spatial dimensions. The two-point resistivity of the material is then:

$$\rho \equiv \frac{Rwh}{l}$$  \hspace{1cm} (43.9)

where $\rho$ is the resistivity in $\Omega$ m, $R$ is the measured resistance in $\Omega$, and $w$, $h$, and $l$ are the measured physical dimensions of the sample bar in meters.

In practice, measuring resistivity with a two-point technique is often not reliable. There is usually some resistance between the contact wires and the material, or in the measuring equipment itself. These additional resistances make the resistivity of the material measure higher than it really is. A second potential problem is modulation of the sample resistivity due to the applied current. This is often a
possibility for semiconducting materials. A third problem is that contacts between metal electrodes and a semiconducting sample tend to have other electrical properties that give wrong estimates for the actual sample resistivity. The four-point measurement technique overcomes many of these problems.

**Four-Point Technique**

Figure 43.3 shows the four-point measurement technique on a bar of material. Four wires are attached to the sample bar as shown. A current source forces a constant current through the ends of the sample bar. A separate ammeter measures the amount of current $I$ passing through the bar. A voltmeter simultaneously measures the voltage $V$ produced across the inner part of the bar. (Alternatively, a voltage source could apply a voltage across the outer contacts, while an ammeter in series with this voltmeter measures the current flowing through the sample bar.)

The four-point resistivity of the material is then:

$$\rho = \frac{Vwh}{Il_1}$$

where $\rho = \text{Resistivity in } \Omega \text{ m}$  
$V = \text{Voltage measured by the voltmeter in volts}$  
$w = \text{Width of the sample bar measured in meters}$  
$h = \text{Height of the sample bar measured in meters}$  
$I = \text{Current the ammeter measures flowing through the sample in amperes}$  
$l_1 = \text{Distance between the two points where the voltmeter wires make contact to the bar, measured in meters}$

Note that the total length $l$ of the bar is not used to calculate the four-point resistivity: the length $l_1$ between the two inner contacts is used.

**Common Experimental Errors**

There are many experimental pitfalls to avoid when making resistivity measurements. The most common sources of error arise from doing a two-point measurement on a material that has any of the contact problems discussed earlier. For this reason, it is advisable to do four-point measurements whenever possible. This section describes experimental techniques to avoid errors in measuring resistivity:

1. The most difficult part of making resistivity measurements is often making good electric contacts to the sample. The general technique for making good electric contacts is to clean the areas of the sample where contacts are to be made with alcohol or an appropriate solvent, and then apply the contacts. If this does not work, try scraping the surface with a razor blade where contact is to be made, or cutting the sample to expose a fresh surface. Contacts can be made in many ways, such as using alligator clips, silver-paint, squeezing a wire against the material, soldering wires to the
material, pressing small pieces of indium or a similar soft metal onto the contact areas, etc. Contacts can age: a good contact can become a bad contact over time. It might be necessary to make fresh contacts to a sample that has aged. There are many complications involved in the electrical properties of contacts. Refer to the sources listed at the end of this chapter for more extensive discussions.

2. The measurement system should be calibrated before measuring any material samples. Calibration procedures are usually described in the equipment manuals.

3. The input resistance (or “impedance”) of the voltmeter should be at least \(10^5\) higher than the resistance of the sample bar. The input impedance is usually listed in the equipment specifications. Note that some voltmeters and electrometers have a sufficiently high impedance between either of the inputs and ground, but not between the two inputs. In this case, it is necessary to use two voltmeters/electrometers (each with one input connected to ground and the other input connected to the sample bar). Measure the difference between them to obtain the voltage across the sample.

4. The measurement system should be tested before measuring any material samples. First test "short" with a thick copper wire or sheet in place of the sample. Then test “open” with nothing in place of the sample. Finally, test with a known, calibrated resistor whose resistance is within an order of magnitude of the sample resistance.

5. The geometry of the sample and electric contacts can be important. Contacts are often made by painting silver-paint or applying metal electrodes to the sample. If these contact areas are large or close to each other, this could reduce the accuracy of the resistivity measurement. It is best to make the two voltage contacts in a four-point measurement as small or thin as possible, and make the distance between inner electrodes much larger than the sample thickness. This also allows a more accurate estimate of the effective volume of the sample being probed.

6. It is critical that the four contacts to the sample bar in a four-point measurement are completely independent; there should be nothing other than the material of the bar connecting each of the four wires at the bar. For example, when pieces of indium are used to attach wires to a small sample, it is easy to smudge two adjacent indium pieces into one another. Those two contacts are no longer independent, and could easily cause errors. Visually inspect the contacts for this condition. If visual inspection is impractical, measure the resistance between the wires going to adjacent contacts. An unusually low resistance might indicate that two contacts are touching each other.

7. The applied voltage or current can cause heating of the material, which can change its resistivity. To avoid this problem, start with very small voltages or currents, and increase until the measured voltages and currents are at least 10 times larger than the random fluctuations of the meters. Then make sure the measured resistance is constant with time: the average resistance should not drift more than 10% in a few minutes.

8. Even if heating of the sample is not a problem, Ohm’s law is not always obeyed. Many materials have a resistance that varies as the applied voltage varies, especially at higher voltages. Test for a linear relationship between current and voltage by measuring the resistance at several voltages on both sides of the measurement voltage. Whenever possible, make measurements in the linear (ohmic) region, where resistance is constant as voltage changes.

9. If one or both of the contacts to the voltmeter are bad, the voltmeter may effectively be disconnected from the material. In this situation, the voltmeter might display some random voltage unrelated to the voltage in the material. It might not be obvious that something is wrong, since this random voltage could accidentally appear to be a reasonable value. Check for this by setting the current source to zero amps and seeing if the voltmeter reading drops to zero volts. If it does not, try remaking the two inner contacts.

10. A critical check of a four-point measurement is to reverse the leads and remeasure the resistance. First, turn the current source to zero amps. Without disturbing any of the four contacts at the sample, swap the two sets of wires going to the voltmeter and the current source/ammeter. The two wires that originally plugged into the voltmeter should now plug into one terminal of the current source and one terminal of the ammeter. The two wires that originally plugged into the
current source and ammeter should now plug into the voltmeter. Turn the current source on and remeasure the resistance. Note that current is now being forced to flow between the two inner contact points on the sample, while the voltage is being measured between the two outer contacts on the sample. The two measured resistances should be within 10% of each other.

11. The resistivity of some materials can depend on how much light is hitting the material. This is especially a problem with semiconductors. If this is a possibility, try blocking all light from the sample during measurement.

Sheet Resistance Measurements

It is often necessary to measure the resistivities of thin films or sheets of various materials. If the material can be made into the form of a rectangle, then the resistivity can be measured just like the bar samples in Figure 43.2:

\[ \rho = \frac{Vwh}{Il} \]  \hspace{1cm} (43.11)

where \( \rho \) = sample resistivity in \( \Omega \cdot m \)
\( V \) = Voltage measured by the voltmeter in volts
\( w \) = Width of the sample measured in meters
\( h \) = Thickness of the sample measured in meters
\( I \) = Current the ammeter measures flowing through the sample in amperes
\( l \) = Length of the film measured in meters

For the special case of a square film, the width \( w \) is equal to the length \( l \), and Equation 43.11 becomes:

\[ \rho_{\text{of square film}} = \frac{Vh}{I} \]  \hspace{1cm} (43.12)

The resistivity of a square film of material is called the “sheet resistivity” of the material, and is usually represented by the symbol \( \rho_s \). The “sheet resistance” \( R_s \) is defined by:

\[ R_s = R_{\text{of square film}} = \frac{V}{I} \]  \hspace{1cm} (43.13)

where \( V \) = Voltage measured by the voltmeter in volts
\( I \) = Current the ammeter measures flowing through the sample in amps

The units for sheet resistance are \( \Omega \), but people commonly use the units “\( \Omega \) per square” or \( \Omega/\square \). The sheet resistance is numerically equal to the measured resistance of a square piece of the material. Note that sheet resistance is independent of the size of the square measured, and it is not necessary to know the film thickness to measure sheet resistance. This makes sheet resistance a useful quantity for comparing different thin films of materials.

It is usually more convenient to measure thin-film samples of arbitrary shape and size. This is usually done by pressing four collinear, equally spaced contacts into a film whose length and width are both much greater than the spacing between contacts. In this situation, the sheet resistance is [3]:

\[ R_s = 4.532 \frac{V}{I} \]  \hspace{1cm} (43.14)

where \( V \) = Voltage measured across the two inner contacts
\( I \) = Current applied through the two outer contacts
In many practical cases, the size of the thin-film sample will not be much greater than the spacing between the four-point contacts. In other cases, it might be necessary to measure a thin film near a corner or edge. In this situation, use geometric correction factors to accurately estimate the sheet resistance. These correction factors are available for the most commonly encountered sample geometries [3].

**Instrumentation for Four-Point Resistivity Measurements**

The resistivities of thin films of materials are often measured using commercial four-point probes. These probes generally have four equally spaced, collinear metal points that are pressed against the surface of the film. A current is applied between the outer two points, while the voltage is measured across the inner two points. These probes can also be used to measure the resistivity of bulk samples. Some companies that make probes and systems specifically for four-point resistivity measurements are listed in Table 43.1.

**Instrumentation for High-Resistivity Measurements**

Many materials such as rocks, plastics, and paper have very high resistivities, up to $1 \times 10^4 \Omega \text{ m}$. The techniques described earlier for measuring resistivity are usually not reliable for these materials. In particular, it is often not possible to make a four-point measurement. One problem is that high voltages are needed to get any measurable current flowing through these materials. A second problem is that very long time constants prevent making steady-state measurements. A third problem is that the surfaces of these materials can often have significantly lower resistivity than the bulk, due to defects or other contamination. Measurements using the techniques described above then give falsely low values for the bulk resistivity. The best way to measure the resistivity of these materials is to use a specialized commercial instrument. These are designed to separate out the bulk resistivity from the surface resistivity, and to minimize the many other problems encountered when measuring very high resistivities. Table 43.2 lists some companies that make high-resistivity measurement systems.

**van der Pauw Technique**

The four-point measurement technique described earlier has assumed the material sample has the shape of a rectangular thin film or a bar. There is a more general four-point resistivity measurement technique that allows measurements on samples of arbitrary shape, with no need to measure all the physical dimensions of the sample. This is the van der Pauw technique [4]. There are four conditions that must be satisfied to use this technique:

1. The sample must have a flat shape of uniform thickness.
2. The sample must not have any isolated holes.
3. The sample must be homogeneous and isotropic.
4. All four contacts must be located at the edges of the sample.

In addition to these four conditions, the area of contact of any individual contact should be at least an order of magnitude smaller than the area of the entire sample. For small samples, this might not be possible or practical. If sufficiently small contacts are not achievable, it is still possible to do accurate van der Pauw resistivity measurements, using geometric correction factors to account for the finite size of the contacts. See Ref. [5] for further details.

The inset illustration of Figure 43.4 illustrates one possible sample measurement geometry. A more common geometry is to attach four contacts to the four corners of a square-shaped sheet of the material. The procedure for doing a van der Pauw measurement is as follows:

1. Define a resistance $R_{ij} = V_{ij}/I_{ij}$, where $V_{ij} = V_i - V_j$ is the voltage between points $k$ and $l$, and $I_{ij}$ is the current flowing from contact $i$ to contact $j$.
2. Measure the resistances $R_{12,34}$ and $R_{32,41}$. Define $R_\text{g}$ as the greater of these two resistances and $R_\text{c}$ as the lesser of these two resistances.

3. Calculate the ratio $R_c/R_c$ and find the corresponding value of the function $f(R_c/R_c)$ from Figure 43.4. Be careful to use the appropriate horizontal scale!

4. Calculate the resistivity $\rho_a$ using:

$$\rho_a = \frac{\pi d (R_c + R_c) f(R_c/R_c)}{\ln 4}$$

(43.15)
FIGURE 43.4 The van der Pauw technique. The inset shows one possible measurement geometry. The graph shows the function $f(R/R_c)$ needed to find the resistivity in Equation 43.15.
where $\rho_a = $ Resistivity in $\Omega \cdot m$

$d = $ Thickness of the sample in m

Resistances $R_a$ and $R_b$ are measured in $\Omega$

$\ln 4 = $ Approximately 1.3863

It is not necessary to measure the width or length of the sample.

5. Switch the leads to measure $R_{3,12}$ and $R_{4,23}$. Repeat steps 3 and 4 to calculate $\rho_b$ using these new values for $R_a$ and $R_b$. If the two resistivities $\rho_a$ and $\rho_b$ are not within 10% of each other, either the contacts are bad, or the sample is too nonuniform to measure reliably. Try making new contacts. If the two resistivities $\rho_a$ and $\rho_b$ are within 10% of each other, the best estimate of the material resistivity $\rho$ is the average:

$$\rho = \frac{(\rho_a + \rho_b)}{2}$$  (43.16)

Note: The function $f(R_a/R_b)$ plotted in Figure 43.4 is defined by the transcendental equation:

$$f\left(\frac{R_a}{R_b}\right) = \frac{-\ln 4 \left(\frac{R_a}{R_b}\right)}{1 + \left(\frac{R_a}{R_b}\right) \ln \left[1 - 4 \left(\frac{R_a}{R_b}\right)^{-1} \right]}$$  (43.17)

Defining Terms

**Conductance:** The inverse of resistance.

**Conductivity:** The inverse of resistivity.

**Contact resistance:** The resistance between the surface of a material and the electric contact made to the surface.

**Four-point technique:** A method for measuring the resistivity of a material, using four electric contacts to the material, which avoids many contact resistance problems.

**Resistance:** The physical property of a particular piece of a material, quantifying the ease with which electricity can flow through it. Resistance will depend on the size and shape of the piece of material.

**Resistivity:** The intrinsic physical property of a material quantifying the ease with which electricity can flow through it. Resistivity will not depend on the size and shape of the piece of material. Higher resistivity means the flow of electricity is more difficult.

**Sheet resistance:** The resistance of a square thin film or sheet of material.

**Two-point technique:** A method for measuring the resistivity of a material, using two electric contacts to the material.

**Van der Pauw technique:** A method of measuring the four-point resistivity of an arbitrarily shaped material sample.

Acknowledgments

I thank Alison Breeze, John Clark, Kirsten R. Daehler, James M. E. Harper, Linda D. B. Kiss, Heidi Pan, and Shukri Souri for many useful suggestions.

Further Information

Electric charge, a basic property of elementary particles, is defined by convention as negative for the electron and positive for the proton. In 1910, Robert Andrews Millikan (1868–1953) demonstrated the quantization and determined the value of the elementary charge by measuring the motion of small charged droplets in an adjustable electric field. The SI unit of charge, the coulomb (C), is defined in terms of base SI units as:

$$1 \text{ coulomb} = 1 \text{ amper}e \times 1 \text{ second}$$ (44.1a)

In terms of fundamental physical constants, the coulomb is measured in units of the elementary charge $e$:

$$1 C = 1.60217733 \times 10^{19} e$$ (44.1b)

where the relative uncertainty in the value of the elementary charge is 0.30 ppm [1].

Charge measurement is widely used in electronics, physics, radiology, and light and particle detection, as well as in technologies involving charged particles or droplets (as for example, toners used in copiers). Measuring charge is also the method of choice for determining the average value for small and/or noisy electric currents by utilizing time integration. The two standard classes of charge-measuring devices are the electrostatic voltmeters and the charge amplifiers.

Electrostatic instruments function by measuring the mechanical displacement caused by the deflecting torques produced by electric fields on charged conductors [2,3]. Electrostatic voltmeters also serve as charge-measurement devices, using the fact that charge is a function of voltage and instrument capacitance. This class of instruments can be optimized for a very wide range of measurements, from about 100 V to 100 kV full-scale, with custom devices capable of measuring voltages in excess of 200 kV. The accuracy of electrostatic voltmeters is about 1% of full scale, with typical time constants of about 3 s. Their insulation resistance is between $10^{10} \Omega$ and $10^{15} \Omega$, with instrument capacitances in the range of 1 pF to 500 pF. Figure 44.1 gives a schematic representation of several types of electrostatic voltmeters.

Modern electronic instruments have replaced in great measure the electrostatic voltmeters as devices of choice for the measurement of charge. The charge amplifier is used for the measurement of charge or charge variation [4]. Figure 44.2 shows the basic configuration of the charge amplifier. The equality of charges on $C_1$ and $C_2$ results in:
This same measurement principle is realized in the electrometer. The charge, $Q$, to be measured is transferred to the capacitor, $C$, and the value, $V$, of the voltage across the capacitor is measured: $Q = CV$. Figure 44.3 shows the block diagram for the typical digital electrometer [5]. Charge is measured in the coulomb mode, in which a capacitor $C_f$ is connected across the operational amplifier, resulting in the input capacitance $AC_f$. Typical gain $A$ for these amplifiers is in the range $10^4$ to $10^6$, making $AC_f$ very large, and thus eliminating the problem of complete charge transfer to the input capacitor of the coulombmeter. Electrometers have input resistances in the range $10^{14}$ to $10^{16}$ $\Omega$, resulting in very long time constants, and thus minimizing the discharging of the capacitor. Typical leakage currents are $5 \times 10^{-14}$ A to $5 \times 10^{-16}$ A, again minimizing the variation in the charge. In the coulombmeter mode, electrometers can measure charges as low as $10^{-15}$ C and currents as low as $10^{-17}$ A.

Errors in charge-measuring instruments are caused by extraneous currents [5]. These currents are generated as thermal noise in the shunt resistance, by resistive leakage, and by triboelectric, piezoelectric, pyroelectric, electrochemical, and dielectric absorption effects. The coulombmeter function of the electrometers does not use internal resistors, thus eliminating this thermal noise source. Triboelectric charges due to friction between conductors and insulators can be minimized by using low-noise triaxial cables, and by reducing mechanical vibrations in the instrument. Under mechanical stress, certain insulators
will generate electric charge due to piezoelectric effects. Judicious choices of materials and reduction of stress and mechanical motion can significantly reduce this effect. Trace chemicals in the circuitry can give rise to electrochemical currents. It is therefore important to thoroughly clean and dry chemicals of all sensitive circuitry. Variations in voltages applied across insulators cause the separation and recombination of charges, and thus give rise to dielectric absorption parasitic currents. The solution is to limit the voltages applied to insulators used for high-sensitivity charge measurements to less than about 5 V.

Dielectric materials used in sensitive charge-measurement experiments should be selected for their high resistivity (low resistive leakage), low water absorptivity, and minimal piezoelectric, pyroelectric, triboelectric, and dielectric absorption effects. Sapphire and polyethylene are two examples of suitable materials.

Guarding is used to minimize both shunt currents and errors associated with the capacitance of cables and connectors. The block diagram in Figure 44.3 shows typical guarding arrangements for modern electrometers.

44.1 Electrostatic Voltmeters

Electrostatic voltmeters and the more sensitive mechanical electrometers use an indicator to readout the position of a variable capacitor. Depending on their mechanical configuration, the electrostatic voltmeters can be categorized into three types: repulsion, attraction, and symmetrical [2, 3]. The moving system in the high-sensitivity instruments is suspended from a torsion filament, or pivoted in precision bearings to increase ruggedness. A wide variety of arrangements is used for the capacitative elements, including parallel plates, concentric cylinders, hinged plates, and others. Motion damping of the moving parts is provided by air or liquid damping vanes or by eddy current damping.

One of the oldest devices used to measure charge is the gold leaf electroscope, shown in Figure 44.1a. Thin leaves of gold are suspended from a conductive contact that leads out of a protective case through an insulator. As charge applied to the contact is transferred to the leaves, the leaves separate by a certain

FIGURE 44.3 Conceptual block diagram of the digital electrometer. In the coulombs function, the charge to be determined is transferred to the corresponding capacitor, and the voltage across this capacitor is measured.
angle, the mutual repulsion being balanced by gravity. In principle, this device can also be used to measure the voltage difference between the contact electrode and the outer case, assuming the capacitance as a function of leaf separation angle is known. The electroscope is an example of a repulsion-type device, as is the Braun voltmeter in which the electroscope leaves are replaced by a balanced needle [2]. The delicate nature and low accuracy of this class of instruments limit their use in precise quantitative measurement applications.

An example of an attraction electrostatic voltmeter used for portable applications is shown in Figure 44.1b. While the fixed sector disk is held at \( V_1 \), the signal \( V_2 \) is applied to the movable sector disk through a coil spring that supplies the balancing torque. Opposite charges on the capacitor cause the movable plate to rotate until the electric attraction torque is balanced by the spring. If a voltage \( V = V_1 - V_2 \) is applied, the electric torque is given by [3]:

\[
\tau = \frac{dU}{d\theta} = \frac{1}{2} \left( \frac{C V^2}{V_1 - V_2} \right) = \frac{1}{2} V_1 \frac{dC}{d\theta}
\]

(44.3)

The balancing spring torque is proportional to angular displacement, so the angle at equilibrium is given by:

\[
\frac{1}{2} V^2 \frac{dC}{d\theta} = K\theta
\]

(44.4)

Since the rotation is proportional to \( V^2 \), such an instrument can be used to measure ac voltages as well.

Symmetrical instruments are used for high-sensitivity, low-voltage measurements. The voltage is applied to a mobile element positioned between a symmetrical arrangement of positive and negative electrodes. Common mode displacement errors are thus reduced, and the measurement accuracy increased. One of the first devices sensitive enough to be called an “electrometer,” was the quadrant electrometer shown schematically in Figure 44.1c. As a voltage difference, \( V_1 - V_2 \), is applied across the quadrant pairs, the indicator is attracted toward one pair and repelled by the other. The indicator is suspended by a wire allowing the stiffness of the suspension to be controlled by the potential \( V_i \) so that the displacement is given by [2]:

\[
\theta = K \left[ \left( V_i - V_2 \right) \left( -V_i + \frac{1}{2} \left( V_i - V_2 \right) \right) \right]
\]

(44.5)

where \( K \) is the unloaded spring constant of the suspension.

The advantage of electrostatic instruments is that the only currents they draw at dc are the leakage current and the current needed to charge up the capacitive elements. High-performance symmetrical electrostatic instruments have leakage resistances in excess of \( 10^{16} \) \( \Omega \), sensitivities of better than 10 \( \mu \)V, and capacitances of 10 pF to 100 pF. They are capable of measuring charges as small as \( 10^{-19} \) C, and are sensitive to charge variations of \( 10^{-19} \) C.

Historically, as stated above, the symmetrical electrostatic voltmeters have been called “electrometers.” Note that this can give rise to some confusion, as the term electrometer is presently also used for the electronic electrometer. This is a high-performance dc multimeter with special input characteristics and high sensitivity, capable of measuring voltage, current, resistance, and charge.

Modern noncontacting electrostatic voltmeters have been designed for voltage measurements up to the 100-kV range. An advantage of these instruments is that no physical or electric contact is required between the instrument and test surface, ensuring that no charge transfer takes place. Kawamura, Sakamoto, and
Noto [6] report the design of an attraction-type device that uses a strain gage to determine the displacement of a movable plate electrode. Hsu and Muller [7] have constructed a micromechanical shutter to modulate the capacitance between the detector electrode and the potential surface to be measured. Trek Inc. [8] electrostatic voltmeters achieve a modulated capacitance to the test surface by electromechanically vibrating the detector electrode. Horenstein [9], Gunter [10], and MacDonald and Fallone [11] have employed noncontacting electrostatic voltmeters to determine the charge distributions on semiconductor and insulator surfaces. Tables 44.1 and 44.2 contain a selection of available commercial devices and manufacturers.

### 44.2 Charge Amplifiers

The conversion of a charge, \( Q \), into a measurement voltage involves at some stage the transfer of that charge onto a reference capacitor, \( C_r \). The voltage, \( V_r \), developed across the capacitor gives a measure of the charge as \( Q = V_r / C_r \). There are two basic amplifier configurations for carrying out such measurements using the reference capacitor in either a shunt or feedback arrangement.

\(^a\) Available in a range of specifications.
Figure 44.4 shows a typical circuit in which the reference capacitor is used in a shunt mode. In this example, it is assumed that the charge that is to be measured is the result of the integrated current delivered by a time-dependent current source, \( i(t) \). With the measurement circuit disconnected (switch in position s2), the charge on the source capacitor, \( C_s \), at time \( t \) will be \( Q = \int_0^t i(t) dt \) (assuming \( Q \) starts from zero at \( t = 0 \)) and the output voltage, \( V_o \), will be zero, as the input voltage to the (ideal) operational amplifier is zero. On closing the switch in position s1, the charge on \( C_s \) will then be shared between it and \( C_r \) and:

\[
V_o = \left( \frac{R_s + R_1}{R_2} \right) \frac{Q}{C_s + C_r} \tag{44.6}
\]

In order to accurately relate the output voltage to the charge \( Q \) not only does the gain of the noninverting amplifier and the reference capacitance need to be known, which is relatively straightforward,
but it is also necessary to know the source capacitance. This is not always easy to determine. The effect of any uncertainty in the value of $C_s$ can be reduced by increasing the value of the reference capacitor to the point where it dominates the total capacitance. However, in so doing, the output voltage is also reduced and the measurement becomes more difficult. The dependence of the measurement on $C_s$ is one of the main limitations to this simple method of charge measurement. In addition, any leakage currents into the input of the operational amplifier, through the capacitors, or back into the source circuitry during the measurement period will affect the result. For the most accurate measurements of low charge levels, feedback amplifiers are more commonly used.

**Feedback Amplifiers**

Figure 44.5 shows a circuit where the reference capacitor now provides the feedback path around the operational amplifier. The output voltage from this configuration for a given charge $Q$ transfer from the source is then:

$$V_0 = \frac{A Q}{C_s + AC_r}$$

where $A$ is the open-loop gain of the operational amplifier. For most situations, $AC_r > C_s$ and the charge measurement becomes independent of the source capacitance. In addition, the inverting input to the operational amplifier is kept close to ground potential, reducing the magnitude of leakage currents in that part of the circuit. However, in contrast to these two benefits is the new problem that the input bias current for the operational amplifier is integrated by the feedback capacitor, producing a continual drift in the output voltage. Several solutions have been used to overcome this problem, including the use of a parallel feedback resistor, $R_f$, which suppresses the integrating behavior at low frequencies (periods longer than $R_f C_r$), balancing the bias current with another externally provided current, and incorporating a reset switch that discharges the circuit each time the output voltage ramps beyond a set trigger level.

The sensitivity of feedback amplifiers depends on the noise sources operating within any specific application. The most impressive performance is obtained by amplifiers integrated into CCD chips (charge coupled devices) that can, under the right operational conditions, provide sensitivities measured in terms of a few electron charges. To illustrate the important parameters involved in the design of ultra-low noise charge preamplifiers for CCD-type applications, consider the circuit shown in Figure 44.6. The source (detector) is now shown as a biased photodiode, which is assumed to be producing individual bursts of charge each time a photon (an X-ray, for example) interacts in it. In this example, the photodiode is coupled to the amplifier using a large value capacitor, $C_c$. This blocks the direct current path from the diode bias supply, $V_b$, but provides a low impedance path for the short-duration charge deposits. The preamplifier is a variant on that shown in Figure 44.5, in which there is now a parallel feedback resistor to provide baseline restoration on long time scales and an FET transistor to reduce the effect of the operational amplifier input bias current by virtue of its high current gain factor, $\beta$.  

---

© 1999 by CRC Press LLC
In practice, the dominant noise contributions in most applications of this type come from Johnson (current) noise in the bias and feedback resistors, shot noise on the photodiode bias current, voltage noise across the FET, and finally the inevitable $1/f$ component. The two resistors effectively feed thermal current noise into the input of the integrator. Similarly, the shot noise associated with the photodiode bias current feeds into the input. Together, these components are known as parallel noise and the total parallel noise charge is given by:

$$ q_p = \sqrt{\frac{4kT}{R_f + R_b}} + \frac{2eI_b(T)}{\Delta B} $$  \hspace{1cm} (44.8) 

where $k$ is Boltzmann’s constant, $e$ is the charge on the electron, $T$ is absolute temperature, and $\Delta B$ is the bandwidth associated with the measurement that will depend on the details of subsequent shaping amplifier stages [12]. Voltage noise across the FET (and hence operational amplifier inputs) will arise from junction noise in the FET itself and from Johnson noise in its bias resistor, $R_b$. In practice, the FET junction noise usually dominates, in which case this series noise contribution is given by:

$$ q_s = \sqrt{\epsilon_n^2 C_m^2 \Delta B} $$  \hspace{1cm} (44.9) 

where $\epsilon_n$ is the junction voltage noise for the FET in V/$\sqrt{\text{Hz}}$ and $C_m$ is the total capacitance seen at the gate of the FET. This will include both the source capacitance, the gate capacitance of the FET, and any stray capacitance. The total noise is then the quadrature sum of Equations 44.8 and 44.9. The different dependencies on the bandwidth for Equations 44.8 and 44.9 imply there will be some optimum bandwidth for the measurement and this will depend on the relative contributions from each. $1/f$ noise manifests itself as a bandwidth-independent term that again, must be added in quadrature. The Johnson noise associated with the resistors and FET junction will show a temperature dependence decreasing with $\sqrt{T}$. For the FET, this reduction does not continue indefinitely and there is usually an optimum temperature for the FET around 100 K. Photodiode bias currents also fall with decreasing temperature and, for silicon devices, this is about a factor of 2 for every 10-K drop in temperature. Most ultralow noise

---

**FIGURE 44.6** Typical ultralow noise charge preamplifier configuration for charge pulse readout from ionization type radiation detectors (e.g., X-ray detection using photodiodes or CCDs). The large capacitor $C_c$ provides a low impedance path for the short charge deposit pulses, while the parallel feedback resistor provides baseline restoration on long time scales. An FET transistor reduces the effect of the operational amplifier input bias current.
applications thus operate at reduced temperature, at least for the sensitive components. Bias resistors and feedback resistors are kept as high as possible (typically > 100 MΩ) and FETs are specially selected for low junction voltage noise (typically 1 nV/√Hz). Ideally, photodiode capacitances should be kept as low as possible and there is also an interplay between the FET junction noise, \( \varepsilon_n \), and the FET gate capacitance that is affected by altering the FET bias current, which can be used to fine-tune the series noise component.

Finally, there is another noise component that can often be critical and difficult to deal with. This is from microphonics. There are two effects. First, the feedback reference capacitor is typically made as small as possible (<1 pF) to reduce the effect of noise in the following shaping amplifier stages. This makes it sensitive to any stray capacitances and, if there are vibrations in the system that alter the local geometry, then this can change the feedback capacitance that changes the “gain” of the preamplifier. Second, the photodiode will be operating with some applied bias voltage (often several tens of volts) and any change in its apparent capacitance through mechanical movement of components will result in charge being moved around. These charge movements will be sensed by the charge amplifier. Ultralow noise applications that ignore mechanical stability in their design phase are in peril. Tables 44.1 and 44.2 contain a selection of available commercial devices and manufacturers.

### 44.3 Applications

The Millikan technique of measuring charges on particles suspended in electric fields continues to be developed for various applications. Kutsuwada et al. [13] use a modified Millikan experiment to measure the charge distribution on electrophotographic toner particles of various sizes. They show a comparison of the results obtained using an ordinary Millikan apparatus, and a modified system in which an additional ac electrode has been inserted in the hyperbolic quadrupole electrode assembly. The two methods agree to within a small multiplicative calibration factor. A different method of measuring the charge of toner particles uses the \( q/d \) meter [14] in which \( q \) and \( d \) refer, respectively, to the charge and the diameters of the particles. In the \( q/d \) meter, the charged particles are transported horizontally in a steady laminar air flow, and move vertically in an electric field until deposited on a registration electrode. The position at which the particle is deposited on the registration electrode defines the charge-to-diameter ratio. The size of the deposited particle is then measured, thus completing the determination of the charge distribution for various particle sizes.

The experiments searching for fractional charges [15] make use of superconducting niobium spheres 0.25 mm in diameter, suspended in vacuum at 4.2 K in a magnetic field. The vertical position of the spheres is modulated by an alternating electric field and measured with an ultra-sensitive magnetometer. Positrons and electrons generated by radioactive sources are used to cancel all integer charges on the spheres. Fractional charges are detected and measured as that residual charging of the niobium spheres that cannot be neutralized by the integral charges from the radioactive sources. Although this experiment is sensitive to about 0.01 electron charges (\( 10^{-21} \) C), it has produced no conclusive evidence of fractional charges.

A similar approach, using force modulation, is used for the noncontact measurement of charge on gyroscopes [16]. Out-of-phase equal forces are applied to an electrostatically suspended gyroscope at a frequency well within the suspension control bandwidth. The charge of the gyroscope is then proportional to modulation frequency component of the suspension control effort. The sensitivity of this method is about \( 10^{-12} \) C gyroscope charge, limited by the allowable modulation force and position sensor noise.

Noncontact measurement of charge on liquid drops in a microgravity environment can be also performed using field mill instruments [17]. A mechanical chopper is used to modulate the electric field induced by the spherical charge on a grounded sensing plate. The resulting alternating current from sensor to ground is a measure of the charge on the drop. In a refinement of this method, the modulation is achieved by varying the distance between charge and sensor. The authors [18] claim that this system provides an increase in sensitivity of 2 to 3 orders of magnitude over the original technique.
Optical sensors based on the Pockels effect [19] are used to measure the space-charge field in gaseous dielectrics. The Pockels effect involves the change in the birefringence of certain crystalline materials on the application of an electric field. In the measuring system, a circularly polarized beam is detected after passing through the Pockels sensor and a polarizing plate. The detected intensity varies linearly with the intensity of the electric field applied to the sensor. This system is capable of performing a vector measurement of the electric field produced by the space charge, determining both intensity and direction.

Optical methods of charge measurement are also used for particles whose physical structure depends on their charge. An example is the degree of dissociation of the end groups of polystyrene particles in colloidal solutions [20]. In this application, the intensities of the Raman scattering spectrum lines depend on the degree of dissociation of the polystyrene end groups, and thus determine the charge of these particles.

A widely used application of charge measurement is as an integral element of radiation dosimetry. Radiation is passed through ionization chambers, where the generated ions are collected and the charge measured with electrometers. Ionization chambers used in dosimetry for radiation therapy have typical sensitivities in the range 0.02 nC R⁻¹ to 0.2 nC R⁻¹. Coulombmeter electrometers with sensitivities of 1 pC to 10 pC are therefore required for this application.

**Defining Terms**

**Charge**, also **Electric charge**: A basic property of elementary particles, defined by convention as negative for the electron and positive for the proton. The SI unit of charge is the coulomb (C), defined as 1 ampere × 1 second.

**Electrostatic instrument**: An instrument that functions by measuring the mechanical displacement or strain caused by electric fields.

**Electrostatic voltmeter**: Electrostatic instrument used to measure charge. The charge is determined as a function of voltage and instrument capacitance.

**Charge amplifier**: Charge-measuring instrument. The charge is transferred to a reference capacitor and the resulting voltage across the capacitor is measured. Shunt and feedback versions of the charge amplifier have the reference capacitor used in shunt and feedback mode, respectively.

Curtin University of Technology

45.2 Characteristics of Capacitors

Selection of Capacitors and Capacitor Reliability • Capacitor Standard Values and Tolerances • Capacitors as Circuit Components • Capacitive Bridges and Measurement of Capacitance

A capacitor is a system of two conducting electrodes, having equal and opposite charges separated by a dielectric. The capacitance $C$ of this system is equal to the ratio of the absolute value of the charge $Q$ to the absolute value of the voltage between bodies as:

$$C = \frac{Q}{V}$$  \hspace{1cm} (45.1)

where $C = \text{Capacitance in farad (F)}$
$Q = \text{Charge in coulomb (C)}$
$V = \text{Voltage (V)}$

The unit of capacitance, the farad, is a large unit; practical capacitors have capacitances in microfarads ($\mu$F or $10^{-6}$ F), nanofarads (nF or $10^{-9}$ F), and picofarads (pF or $10^{-12}$ F). The unit conversions are shown in Table 45.1.

The capacitance $C$ depends on the size and shape of charged bodies and their relative positions; examples are shown in Table 45.2. Generally, capacitance is inherent wherever an electrostatic field appears. In many electronic systems, it is necessary to deal with capacitances that are designed within the circuits and also with unwanted interference and stray capacitances that are introduced externally or internally at various stages of the circuits. For example, some sensors operate on capacitive principles, giving useful signals; in others, capacitance is inherent but undesirable. In many cases, cables and external

\[ C = \frac{\varepsilon A}{d} \]

\( \text{where } r \text{ value is the volumetric ratio} \)

**Parallel planes with two constituent dielectrics**

\[ C = \frac{\varepsilon A}{d_1 + d_2} \]

\[ \frac{\varepsilon_1}{\varepsilon_2} \]

**Parallel planes with two different dielectrics**

\[ C = \frac{4\pi\varepsilon\ell}{\ln\left(\frac{r_2}{r_1}\right)} \]

**Coaxial cylinders with single dielectric**

\[ C = \frac{2\pi\varepsilon_0\ell}{\ln\left(\frac{r_1}{r_2}\right) + \frac{r_2}{r_1}\frac{d_2}{d_1}\frac{\varepsilon_3}{\varepsilon_1}} \]

\[ = \left(\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3}\right)^{-1} \]

**Coaxial cylinders with three dielectrics**

\[ C = \frac{\pi\ell}{\ln\left(\frac{d}{r} + \left(\frac{d}{r}\right)^2 - 1\right)} = \frac{2\pi\ell}{\cosh^{-1}\left(\frac{d}{r}\right)} \]

© 1999 by CRC Press LLC
circuits introduce additional capacitances that need to be accounted for the desirable operation of the system. In these cases, Table 45.2 is useful to identify and analyze possible sources of capacitances where charged bodies are involved.

In general, the capacitance can be determined by solving Laplace's equations $\nabla^2 V(x,y,z) = 0$ with appropriate boundary conditions. One type of boundary condition specifies the electrode voltages $V_1$ and $V_2$ of the plates. Laplace's equation yields to $V$ and the electric field $E(x,y,z) = -\nabla V(x,y,z)$ between the electrodes. The charge of each electrode can also be obtained by integration of the flux density over each electrode surface as:

$$Q = \int \varepsilon(x,y,z) E(x,y,z) \, dA$$  \hspace{1cm} (45.2)$$

If the capacitor is made from two parallel plates, as shown in Figure 45.1, the capacitance value in terms of dimensions can be expressed by:

$$C = \varepsilon A/d = \varepsilon_r \varepsilon_0 A/d$$  \hspace{1cm} (45.3)$$

where $\varepsilon = \text{Dielectric constant or permittivity}$

$\varepsilon_r = \text{Relative dielectric constant (in air, } \varepsilon_r = 1)$
$\varepsilon_0 = \text{Dielectric constant of vacuum} \ (8.854188 \times 10^{-12} \text{ F m}^{-1})$

$d = \text{Distance of the plates in m}$

$A = \text{Effective area of the plates in m}^2$

In arriving to Equation 45.3, the fringe field is neglected for small distances, $d$, between the plates.

Capacitances can also be expressed in terms of dielectric properties currents and voltages. Suppose that a uniform dielectric between two parallel plates has a resistance, $R$, which can be written as:

$$R = d \rho / A \quad (45.4)$$

where $\rho$ is the specific resistance of the dielectric in $\Omega \text{ m}$. Then, using Equation 45.3 gives:

$$C = \varepsilon \rho / R \quad (45.5)$$

A voltage $V$ across the capacitor causes a leakage current $I_l = V / R$ such that:

$$C = \varepsilon \rho I_l / V \quad (45.6)$$

This indicates that the leakage current of a capacitor is proportional to its capacitance value.

As seen in Equations 45.3 and 45.4, the value of the capacitance is proportional to the permittivity of the dielectric material used. In the construction of capacitors, the permittivity of commonly used materials is given in Table 45.3.

### 45.1 Types of Capacitors

Commonly used fixed capacitors are constructed with air, paper, mica, polymers, and ceramic dielectric materials. A comprehensive list of common capacitors and their characteristics are given in Table 45.4(a) and Table 45.4(b) and a list of manufacturers is given in Table 45.5. Variable capacitors are generally made with air or ceramic dielectric materials. The capacitors used in electronic circuits can be classified as: low-loss, medium-loss, and high-tolerance capacitors.
Low-loss capacitors such as mica, glass, low loss ceramic and low-loss plastic film capacitors generally have a good capacitance stability. These capacitors are expensive and often selected in precision applications, e.g., telecommunication filters.

Medium-loss capacitors have medium stability in a wide range of ac and dc applications. These are paper, plastic film, and medium-loss ceramic capacitors. Their applications include, coupling, decoupling, bypass, energy storage, and some power electronic applications (e.g., motor starter, lighting, power line applications, and interference suppressions).

High-tolerance capacitors such as aluminum and tantalum electrolytic capacitors deliver high capacitances. Although these capacitors are relatively larger in dimension, they are reliable and have longer service life. They are used in polarized voltage applications, radios, televisions and, other consumer goods, as well as military equipment and harsh industrial environments.

There are also specially designed capacitors (e.g., mica, glass, oil, gas and vacuum). These capacitors are used particularly in high-voltage (35 kV) and high-current (200 A) applications.

In the majority of cases, the manufacturing process of the capacitors begins by forming one plate using metallization of one side of a flexible dielectric film. A foil such as aluminum is used as the other plate. The film/foil combination is rolled on a suitable core with alternate layers slightly extended and then heat-treated. In some cases, two-foil layers are divided by a dielectric film or paper impregnated with oil.

Generally, capacitors are two-terminal devices with one electrode as the ground terminal. However, if both terminals are separated from the common terminal, the additional capacitances between ground and electrodes might have to be taken into account. Usually, capacitance between electrodes and ground are small compared to the dominant capacitance between plates. Three-terminal capacitances exist and are manufactured in many different ways, as illustrated in Table 45.2.

As far as construction and materials and construction techniques are concerned, the capacitors can broadly be classified as: electrolytic, ceramic, paper, polymer, mica, variable capacitors, or integrated circuit capacitors.

**Paper capacitors:** Usually, paper capacitors are made with thin (5- to 50-μm in thickness) wood pulp. A number of sheets are used together to eliminate possible chemical and fibrous defects that may exist in each sheet. The paper sheets are placed between thin aluminum foils and convolutely wound, as shown in Figure 45.2. The moisture of the paper is removed at high-temperature vacuum drying before the capacitor is vacuum impregnated with oil, paraffin, or wax. The losses and self-inductance are sizeable and frequency dependent. The applications are usually restricted to low frequency and high voltages. When impregnated with silicone-oil, they can withstand voltages up to 300 kV.

**Electrolytic capacitors:** This describes any capacitor in which the dielectric layer is formed by an electrolytic method. The electrolytic capacitors in dry foil form may be similar to construction to paper film capacitors; that is, two foil layers separated by an impregnated electrolyte paper spacer are rolled together. In this case, one of the plates is formed using metallization of one side of a flexible dielectric

film. A foil (e.g., aluminum) is used as the plate. The capacitor is then hermetically sealed in an aluminum or plastic can, as shown in Figure 45.3. These capacitors can be divided into two main subgroups.

**Tantalum electrolytic**: The anode consists of sintered tantalum powder and the dielectric is \( \text{Ta}_2\text{O}_5 \), which has a high value of \( \varepsilon_r \). A semiconductor layer \( \text{MnO}_2 \) surrounds the dielectric. The cathode made from graphite is deposited around \( \text{MnO}_2 \) before the capacitor is sealed. The form of a tantalum electrolytic capacitor includes a porous anode slug to obtain a large active surface. These capacitors are highly stable and reliable, with good temperature ranges, and are suitable for high-frequency applications.

**Aluminum electrolytic capacitors**: Aluminum foil is oxidized on one side as \( \text{Al}_2\text{O}_3 \). The oxide layer is the dielectric having a thickness of about 0.1 \( \mu \text{m} \) and a high electric field strength \( (7 \times 10^5 \text{ Vmm}^{-1}) \). A second layer acting as the cathode, made from etched Al-foil, is inserted. The two layers are separated by a spacer when the layers are rolled and mounted.

Electrolytic capacitors must be handled with caution, since in these capacitors the electrolytic is polarized. That is, the anode should always be positive with respect to the cathode. If not connected correctly, hydrogen gas will form; this damages the dielectric layer, causing a high leakage current or

blow-up. These capacitors can be manufactured in values up to 1 F. They are used in not so critical applications such as coupling, bypass, filtering, etc. However, they are not useful at frequencies above 1 kHz or so.

Ceramic and glass capacitors: The dielectric is a ceramic material with deposited metals. They are usually rod or disk shaped. They have good temperature characteristics and are suitable in many high-frequency applications. There are many different types, such as (1): Low K ceramic: These capacitors are made with materials that contains a large fraction of titanium dioxide (TiO₂). The relative permittivity of these materials varies from 10 to 500, with negative temperature coefficient. The dielectric is TiO₂ + MgO + SiO₂, suitable in high-frequency applications in filters, tuned circuits, coupling and bypass circuits, etc. (2): High K ceramic: The dielectric contains a large fraction of barium titanate, BaTiO₃, mixed with PbTiO₃ or PbZrO₃, giving relative permittivity of 250 to 10,000. They have high losses, and also have high-voltage time dependence with poor stability. (3): Miniature ceramic capacitors: These are used in critical high-frequency applications. They are made in the ranges of 0.25 pF to 1 nF. (4): Dielectric ceramic capacitors: The material is a semiconducting ceramic with deposited metals on both sides. This arrangement results in two depletion layers that make up the very thin dielectric. In this way, high capacitances
can be obtained. Due to thin depletion layers, only small dc voltages are allowed. They are used in small and lightweight equipment such as hearing aids.

Glass capacitors are made with glass dielectric materials. The properties of glass dielectrics are similar to ceramic materials.

**Polymer capacitors:** Various polymers, such as polycarbonate, polystyrol, polystyrene, polyethylene, polypropylene, etc., are used as the dielectric. The construction is similar to that of paper capacitors. Polystyrene capacitors, in particular, are very stable, and are virtually frequency independent. They have low voltage ratings and are used in transistorized applications as tuning capacitors and capacitance standards.

**Mica capacitors:** A thin layer of mica, usually muscovite mica (≥0.003 mm) are stapled with Cu-foil or coated with a layer of deposited silver. They are then vacuum impregnated and coated with epoxy. The field strength of these capacitors is very high (10⁴ V mm⁻¹) and resistivity $\rho = 10^6$ to $10^{15}$ Ω m. These capacitors are available in values from 1.0 pF to several microfarads for high voltage (from 100 V to 2000 V) and high-frequency applications. They have tolerances between ±20% and ±0.5%.

**Variable capacitors:** These capacitors usually have air as the dielectric and consist of two assemblies of spaced plates positioned together by insulation members such that one set of plates can be rotated. A typical example of variable capacitors is given in Figure 45.4. Their main use is the adjustment of resonant frequency of tuned circuits in receivers and transmitters, filters, etc. By shaping the plates, various types of capacitances can be obtained, such as: linear capacitance, in which capacitance changes as a linear function of rotation, and logarithmic capacitance.

Variable capacitors can be grouped as: precision types, general-purpose types, transmitter types, trimmer types, and special types such as phase shifters.

Precision-type variable capacitors are used in bridges, resonant circuits, and many other instrumentation systems. The capacitance swing can be from 100 pF to 5000 pF. They have excellent long-term stability with very tight tolerances.

General-purpose type variable capacitors are used as tuning capacitors in radio and other broadcasting devices. They are available in many laws such as, straight line frequency, straight line wavelength, etc. The normal capacitance swing is from 400 pF to 500 pF. In some cases, a swing of 10 pF to 600 pF are available.

Transmitter-type variable capacitors are similar to general-purpose variable capacitors, but they are specially designed for high-voltage operations. The vanes are rounded and spaced wider to avoid flashover and excessive current leakages. The swing of these capacitors can go from few picofarads up to 1000 pF. In some cases, oil filling or compressed gases are used to increase operating voltages and capacitances.

---

**FIGURE 45.4** A variable capacitor. It consists of two assemblies of spaced plates positioned together by insulation members such that one set of plates can be rotated. The majority of variable capacitors have air as the dielectric. They are used mainly in adjustment of resonant frequency of tuned circuits in receivers and transmitters. By shaping the plates suitably, they can be made to be linear or logarithmic.
Trimmer capacitors are used for coil trimming at intermediate radio frequencies. They can be air-spaced rotary types (2 pF to 100 pF), compression types (1.5 pF to 2000 pF), ceramic-dielectric rotary types (5 pF to 100 pF), and tubular types (up to 3 pF).

Sometimes, special type variable capacitors are produced for particular applications, such as differential and phase shift capacitors in radar systems. They are used for accurate measurement of time intervals, high-speed scanning circuits, transmitters and receivers, etc.

**Integrated circuit capacitors:** These are capacitors adapted for use in microelectronic circuits. They include some miniature ceramic capacitors, tantalum oxide solid capacitors, and tantalum electrolyte solid capacitors. The ceramic and tantalum oxide chips are unencapsulated and are fitted with end caps for direct surface mounting onto the circuit board. The beam-lead tantalum electrolytic chips are usually attached by pressure bonding. Typical values of these capacitors are: 1 pF to 27 nF for temperature compensating ceramic, (100 to 3000 pF) for tantalum oxide, 390 pF to 0.47 mF for general-purpose ceramic, and (0.1 to 10 µF) for tantalum electrolyte. Operating voltages range from 25 to 200 V for ceramic, 12 to 35 V for tantalum electrolyte and 12 to 25 V for tantalum oxide.

Integrated circuit capacitors are made mostly within MOS integrated circuits as monolayer capacitors containing tantalum or other suitable deposits. The plates of the capacitors of the integrated circuits are generally formed by two heavily doped polysilicon layers formed on a thick layer of oxide. The dielectric is usually made from a thin layer of silicon oxide. These capacitors are temperature stable, with a temperature coefficient of about 20 ppm/°C. Integrated circuit capacitive sensors are achieved by incorporating a dielectric sensitive to physical variables. Usually, the metallization layer formed on top of the dielectric forms a shape to provide access to measured physical variable to the dielectric.

**Voltage variable capacitors:** These capacitors make use of the capacitive effect of the reversed-biased p-n junction diode. By applying different reverse bias voltages to the diode, the capacitance can be changed. Hence, the name, varicap or varactor diodes is given to these devices. Varactors are designed to provide various capacitance ranges from a few picofarads to more than 100 pF. It is also possible to make use of high-speed switching silicon diodes as voltage variable capacitors. However, they are limited by the very low maximum capacitance available. Typical applications of these varactor diodes are in the tuning circuits in radio frequency receivers. Present-day varactor diodes operate into the microwave part of the spectrum. These devices are quite efficient as frequency multipliers at power levels as great as 25 W. The efficiency of a correctly designed varactor multiplier can exceed 50% in most instances. It is also worth noting that some Zener diodes and selected silicon power-supply rectifier diodes can work effectively as varactors at frequencies as high as 144 MHz. In the case of the Zener diode, it should be operated below its reverse breakdown voltage.

### 45.2 Characteristics of Capacitors

Capacitors are characterized by dielectric properties, break-down voltages, temperature coefficients, insulation resistances, frequency and impedances, power dissipation and quality factors, reliability and aging, etc. Typical characteristics of common capacitors are given in Table 45.4.

**Dielectric properties:** Dielectrics of capacitors can be made from polar or nonpolar materials. Polar materials have dipolar characteristics; that is, they consist of molecules whose ends are oppositely charged. This polarization causes oscillations of the dipoles at certain frequencies, resulting in high losses.

In general, capacitor properties are largely determined by the dielectric properties. For example, the losses in the capacitors occur due to the current leakage and the dielectric absorption. These losses are frequency dependent, as typified by Figure 45.5.

The dielectric absorption introduces a time lag during the charging and discharging of the capacitor, thus reducing the capacitance values at high frequencies and causing unwanted time delays in pulse circuits. The leakage current, on the other hand, prevents indefinite storage of energy in the capacitor. An associated parameter to leakage currents is the leakage resistance, which is measured in megohms, but usually expressed in megohm-microfarads or ohms-farads. The leakage resistance and capacitance
introduces time constants that can vary from a few days for polystyrene to several seconds in some electrolytic capacitors. It is important to mention that the leakage current does not only depend on the properties of the dielectric materials, but also depends on the construction and structure of capacitors. This is particularly true for capacitors having values less than 0.1 \( \mu \text{F} \), having very thin dielectric materials between the electrodes.

**Breakdown voltage:** If the capacitor is subjected to high operating voltages, the electric field in the dielectric exceeds the breakdown value, which damages the dielectric permanently. The dielectric strength, which is the ability to withstand high voltages without changing properties, depends on the temperature, frequency, and applied voltage. An example of this dependence on the applied voltage is given in Figure 45.6. It is commonly known that the use of capacitors below their rated values increases the reliability and the expected lifetime. The standard voltage ratings of most capacitors are quoted by the

FIGURE 45.5  Frequency dependence of dielectric loss. The dielectric material of capacitors can be polar or nonpolar. In polar materials, polarization causes oscillations at certain frequencies, resulting in high losses. The dielectric losses introduce a time lag during the charging and discharging of the capacitor, thus reducing the capacitance values at high frequencies.

FIGURE 45.6  Changes in relative permittivity vs. field strength. The dielectric strength depends on the temperature, frequency, and applied voltage. Increases in the applied voltage cause higher changes in the dielectric strength. If the capacitor is subjected to high operating voltages, the electric field in the dielectric exceeds the breakdown value which can damage the dielectric permanently.
manufacturers as 50, 100, 200, 400, and 600 V. Tantalum and electrolytic capacitors have ratings of 6, 10, 12, 15, 20, 25, 35, 50, 75, 100 V and higher.

Usually, values for surge voltages are given to indicate the ability of capacitors to withstand high transients. Typically, the surge voltages for electrolytic capacitors is 10% above the rated voltage, 50% for aluminum capacitors and about 250% for ceramic and mica capacitors.

The rated reverse voltages of electrolytic capacitors are limited to 1.5 V and, in some cases, to 15% of the rated forward voltages.

**Temperature coefficient:** The temperature characteristics of capacitors largely dependent on the temperature properties of the dielectric materials used, as given in Figure 45.7. The temperature coefficients of glass, teflon, mica, and polycarbonate are very small, whereas in ceramic capacitors, they can be very high.

**Insulation resistance:** The insulation resistance of capacitors is important in many circuits. The insulation resistance is susceptible to temperature and humidity. For example, unsealed capacitors show large and rapid changes against temperature and humidity. For most capacitors, under high temperature conditions, the change in insulation resistance is an exponential function of temperature (\( R_{T1} = R_{T2} e^{K(T1-T2)} \)). The temperature dependence of insulation resistance of common capacitors is shown in Figure 45.8.

**Frequency and impedance:** Practical capacitors have increases in losses at very low and very high frequencies. At low frequencies, the circuit becomes entirely resistive and the dc leakage current becomes effective. At very high frequencies, the current passes through the capacitance and the dielectric losses become important. Approximate useable frequency ranges of capacitors are provided in Table 45.4.

An ideal capacitor should have an entirely negative reactance, but losses and inherent inductance prevents ideal operation. Depending on the construction, capacitors will resonate at certain frequencies due to unavoidable construction-based inductances. A typical impedance characteristic of a capacitor is depicted in Figure 45.9.

**Power dissipation and quality factors:** Ideally, a capacitor should store energy without dissipating any power. However, due to equivalent resistances, \( R_{eq} \), some power will be dissipated. The power factor of a capacitor can be expressed as:
where $q$ = Phase angle
$Z_{eq}$ = Equivalent total impedance

**FIGURE 45.8** Temperature dependence of insulation resistance. The insulation resistance of many capacitors is not affected at low temperatures. However, under high temperature conditions, the change in insulation resistance can be approximated by an exponential relation. The insulation resistance is also susceptible to variations in humidity.

**FIGURE 45.9** Frequency and impedance relation of capacitors. The losses and inherent inductance affects the ideal operation of capacitors and the capacitance impedance becomes a function of frequency. Depending on the construction, all capacitors will resonate at a certain frequency.

\[
PF = \cos \theta = \frac{R_{eq}}{|Z_{eq}|}
\]

(45.7)

where $\theta$ = Phase angle
$Z_{eq}$ = Equivalent total impedance
An important characteristic, the dissipation factor of capacitors, is expressed as:

\[
DF = \tan\delta = \frac{R_{eq}}{X_{eq}}
\]  

\(45.8\)

where \(\delta\) = Angle of loss
\(X_{eq}\) = Equivalent reactance

The dissipation factor depends on the frequency. Capacitors are designed such that this dependence is minimal. The measurement of dissipation factor \(\delta\) is made at 1 kHz and 1.0 Vrms applied to the capacitor. A typical dissipation factor curve is depicted in Figure 45.10.

**Selection of Capacitors and Capacitor Reliability**

**Capacitor Selection**

Experience shows that a substantial part of component failures in electronic equipment is due to capacitors. The major cause of this can be attributed to the improper selection and inappropriate applications of capacitors. The following factors are therefore important criteria in the selection of capacitors in circuit applications: (1) the capacitance values and tolerances are determined by operating frequencies or by the value required for timing, energy storage, phase shifting, coupling, or decoupling; (2) the voltages are determined by the type and nature of the source, ac, dc, transient, surges, and ripples; (3) the stability is determined by operating conditions like temperature, humidity, shock, vibration, and life expectancy; (4) the electrical properties are determined by life expectancy, leakage current, dissipation factor, impedance, and self-resonant frequency; (5) the mechanical properties are determined by the types and construction, e.g., size, configuration, and packaging; and (6) the cost is determined by the types and physical dimensions of capacitors and the required tolerance.

**Capacitor Reliability**

Some of the common causes of capacitor failure are due to voltage and current overloads, high temperature and humidity, shock, vibration pressure, frequency effects, and aging. The voltage overload produces an excessive electric field in the dielectric that results in the breakdown and destruction of the dielectric. The current overload caused by rapid voltage variations results in current transients. If these currents are of sufficient amplitude and duration, the dielectric can be deformed or damaged, resulting in drastic...
changes in capacitance values, and thus leading to equipment malfunction. The high temperatures are mainly due to voltage and current overloads. The overheating and high temperatures accelerate the dielectric aging. This causes the plastic film to be brittle and also introduces cracks in the hermetic seals. The moisture and humidity due to severe operating environments cause corrosion, reduce the dielectric strength, and lower insulation resistances. The mechanical effects are mainly the pressure, variation, shock, and stress, which can cause mechanical damages of seals that result in electrical failures. Aging deteriorates the insulation resistance and affects the dielectric strength. The aging is usually determined by shelf-life; information about aging is supplied by the manufacturers.

**Capacitor Standard Values and Tolerances**

General-purpose capacitors values tend to be grouped close to each other in a bimodal distribution manner within their tolerance values. Usually, the tolerances of standard capacitors are 5%, 10%, and 20% of their values, as shown in Table 45.6. Nevertheless, tolerances of precision capacitors are much tighter — in the range of 0.25%, 0.5%, 0.625%, 1%, 2%, and 3% of the values. These capacitors are much more expensive than the standard range.

For capacitors in the small pF range, the tolerances can be given as ±1.5, ±1, ±0.5, ±0.25, and ±0.1 pF. Usually, low tolerance ranges are achieved by selecting manufactured items.

Standard capacitors are constructed from interleaved metal plates using air as the dielectric material. The area of the plates and distance between them are determined and constructed with precision. National Bureau of Standards maintains a bank of primary standard air capacitors that can be used to calibrate the secondary and working standards for laboratories and industry. Generally, smaller capacitance working standards are obtained from air capacitors, whereas larger working standards are made from solid dielectric materials. Usually, silver-mica capacitors are selected as working standards. These capacitors are very stable, have very low dissipation factors and small temperature coefficients, and have very little aging effect. They are available in decade mounting forms.

</tbody>
</table>
The capacitor is used as a two-terminal element in electric circuits with the current–voltage relationship given by:

\[ i(t) = C \frac{dv(t)}{dt} \]  
\[ (45.9) \]

where \( C \) is the capacitance.

This element is represented by the circuit shape as shown in Figure 45.11(a).

From the \( v(t), i(t) \) relationship, the instantaneous power of this element can then be given by:

\[ p(t) = v(t) i(t) \]  
\[ (45.10) \]
The stored energy in the capacitor at time $t$ seconds can be calculated as:

$$w(t) = \int C \, \{\frac{dv(t)}{dt}\} \, dt$$

$$= \left[ \frac{C \, v^2(t)}{2} \right]$$  \hspace{1cm} (45.11)

If the voltage across the capacitor is changing in time, the energy stored in the capacitor in the time interval $t_1$ to $t_2$ can be found using Equation 45.11 as:

$$W = \left( \frac{1}{2} \right) C \left[ v^2(t_2) - v^2(t_1) \right]$$  \hspace{1cm} (45.12)

Although the voltage assumed different values in time interval $t_1$ to $t_2$, if the initial and final voltages are equal (e.g., $v(t_1) = v(t_2)$), the net energy stored in the capacitor will be equal to zero. This implies that the energy stored in the capacitor is returned to the circuit during the time interval; that is, the capacitor transforms the energy without dissipation. The stored energy is associated with the electrostatic field of the capacitor and, in the absence of the electrostatic field, it will be zero.

From the voltage–current relationship in Equation 45.9, it can be seen that a capacitor as a circuit element is a passive component. That is, if the voltage is known, the current can be immediately determined by differentiation. Conversely, if the current is known, then the voltage can be determined by integration. If the voltage $v(t)$ is considered as an input variable, and the current $i(t)$ as an output variable, then the behavior of the current in a certain time interval is completely determined by the behavior of the voltage in this interval. In this case, the solution of the differential equation has the forced component only. Here, the particular solution of the voltage–current differential equation coincides with a full solution and the Laplace transform gives the relationship:

$$I(s) = sC \, V(s)$$ \hspace{1cm} (45.13)

From this, the input–output relationship yields the impedance of the capacitor as:

$$Z(s) = \frac{1}{sC}$$

or

$$Y(s) = sC$$ \hspace{1cm} (45.14)

In the stationary condition, $s \to 0$, and $Z \to \infty$, and $Y \to 0$.

In the sinusoidal condition, $s = j\omega = 2\pi f$, where $f = \text{frequency}$ and, hence:

$$Z(j\omega) = \left[ \frac{1}{j\omega C} \right] = -\frac{j}{\omega C}$$ \hspace{1cm} (45.15)

and
The capacitor can then be characterized under sinusoidal conditions, by a reactance of $X_C = 1/\omega C$ measured in ohms with the current leading the voltage by 90°, as shown in the phasor diagram in Figure 45.11(b).

In sinusoidal operations, the instantaneous power $p(t) = v(t)\cdot i(t)$ can be calculated as:

$$v(t) = V_{\text{max}} \cos \omega t = \sqrt{2} V \cos \omega t$$  \hspace{1cm} (45.17)

Using the relationship given by Equation 45.9, the current can be written as:

$$i(t) = C \frac{dv}{dt} = -\omega C \sqrt{2} V \sin \omega t$$  \hspace{1cm} (45.18)

giving:

$$p(t) = v(t) \cdot i(t) = -2 \omega C V^2 \sin \omega t \cos \omega t = \frac{V^2 \sin 2\omega t}{X_C}$$  \hspace{1cm} (45.19)

This indicates that the average power is zero because of the sin2ωt term, but there is a periodic storage and return of energy and the amplitude of that power is $V^2/X_C$. The power, voltage, and current relationship in a capacitor is given in Figure 45.11(c).

**Series and Parallel Connection of Capacitors**

The formulae for series and parallel connection of capacitors can be obtained from the general consideration of series and parallel connection of impedances as shown in Figures 45.12(a) and (b), respectively. For the series connection, the impedances are added such that:

$$\frac{1}{sC} = \frac{1}{sC_1} + \frac{1}{sC_2} + \cdots + \frac{1}{sC_n}$$  \hspace{1cm} (45.20)

where $C_1$, $C_2$, … $C_n$ are the capacitance of the capacitors connected in series as in Figure 45.12(a). The equivalent capacitance is then given by:

$$C = \left\{ \frac{1}{C_1} + \frac{1}{C_2} + \cdots + \frac{1}{C_n} \right\}^{-1}$$  \hspace{1cm} (45.21)

The final capacitance value will always be smaller than the smallest value.

In a similar way, the equivalent capacitance of parallel connected capacitors is

$$C = C_1 + C_2 + \cdots + C_n$$  \hspace{1cm} (45.22)

and the final value of $C$ is always larger than the largest capacitance in the circuit.

**Distributed Capacitances in Circuits**

Since capacitance is inherent whenever an electric potential exists between two conducting surfaces, its effect will be most noticeable in coils and in transmission lines at high frequencies. In the case of coils,
there are small capacitances between adjacent turns, between turns that are not adjacent, between terminal leads, between turns and ground, etc. Each of the various capacitance associated with the coil stores a quantity of electrostatic energy that is determined by the capacitance involved and the fraction of the total coil voltage that appears across it. The total effect is that the numerous small coil capacitances can be replaced by a single capacitor of appropriate size shunted across the coil terminals. This equivalent capacitance is called either the distributed capacitance or the self-capacitance of the coil, and it causes the coil to show parallel resonance effects under some conditions. In the case of a mismatched or unterminated transmission line, the distributed capacitance, together with the inductive effect, will create a phase difference between the voltage and current in the line. This phase difference depends on the type of termination and the electrical length of the line and, as a result, the input impedance of the line can effectively be an equivalent capacitor when its electrical length is less than a quarter wavelength for an open-circuit termination, or between a quarter wavelength and half a wavelength for a short-circuit termination.

Capacitor Equivalent Circuits

The electric equivalent circuit of a capacitor consists of a pure capacitance \( C_p \), plate inductances \( L_1, L_2 \), plate resistances \( R_1, R_2 \), and a parallel resistance \( R_p \) that represents the resistance of the dielectric or leakage resistance, as shown in Figure 45.13. The capacitors that have high leakage currents flowing through the dielectric have relatively low \( R_p \) values. Very low leakage currents are represented by extremely large \( R_p \) values. Examples of these two extremes are electrolytic capacitors that have high leakage current (low \( R_p \)), and plastic film capacitors, which have very low leakage current (high \( R_p \)). Typically, an electrolytic capacitor might easily have several microamperes of leakage current (\( R_p < 1 \text{ M}\Omega \)), while a plastic film capacitor could have a resistance greater than 100,000 M\( \Omega \).

It is usual to represent a low leakage capacitor (high \( R_p \)) by a series RC circuit, while those with high leakage (low \( R_p \)) are represented by parallel RC circuits. However, when a capacitor is measured in terms of the series \( C \) and \( R \) quantities, it is desirable to resolve them into parallel equivalent circuit quantities. This is because the (parallel) leakage resistance best represents the quality of the capacitor dielectric.
Capacitive Bridges and Measurement of Capacitance

Bridges are used to make precise measurements of unknown capacitances and associated losses in terms of some known external capacitances and resistances. Most commonly used bridges are: series-resistance-capacitance bridge, parallel-resistance-capacitance bridge, Wien bridge, and Schering bridge.

Series-Resistance-Capacitance Bridge

Figure 45.14 is a series-resistance-capacitance (RC) bridge, which is used for the comparison of a known capacitance with an unknown capacitance. The unknown capacitance is represented by \( C_x \) and \( R_x \). A standard adjustable resistance \( R_1 \) is connected in series with a standard capacitor \( C_1 \). The voltage drop across \( R_1 \) balances the resistive voltage drop when the bridge is balanced. The additional resistor in series
with $C_x$ increases the total resistive component, so that small values of $R_1$ will not be required to achieve balance. Generally, the bridge balance is most easily achieved when capacitive branches have substantial resistive components. To obtain balance, $R_1$ and either $R_2$ or $R_4$ are adjusted alternately. This type of bridge is found to be most suitable for capacitors with a high-resistance dielectric and hence very low leakage currents.

At balance:

$$Z_1 Z_3 = Z_2 Z_x$$

(45.23)

Substituting impedance values gives:

$$\left( R_1 - \frac{j}{\omega C_1} \right) R_3 = \left( R_x - \frac{j}{\omega C_x} \right) R_2$$

(45.24)

Equating the real terms gives:

$$R_x = \frac{R_1 R_3}{R_2}$$

(45.25)

and equating imaginary terms gives:

$$C_x = \frac{C_1 R_2}{R_3}$$

(45.26)

An improved version of the series $RC$ bridge is the substitution bridge, which is particularly useful to determine the values of capacitances at radio frequencies. In this case, a series-connected $RC$ bridge is balanced by disconnecting the unknown capacitance $C_x$ and resistance $R_x$, and replacing it by an adjustable standard capacitor $C_s$ and adjustable resistor $R_s$. After having obtained the balance position, the unknown capacitance and resistance $C_x$ and $R_x$ are connected in parallel to the capacitor $C_s$. The capacitor $C_s$ and resistor $R_s$ are adjusted again for the re-balance of the bridge. The changes in the $\Delta C_s$ and $\Delta R_s$ lead to unknown values as:

$$C_x = \Delta C_s$$

and

$$R_x = \Delta R \left( \frac{C_s}{C_x} \right)^2$$

(45.27)

where $C_s$ is the value of $C_s$ in the initial balance condition.

**The Parallel-Resistance-Capacitance Bridge**

Figure 45.15 illustrates a parallel-resistance-capacitance bridge. In this case, the unknown capacitance is represented by its parallel equivalent circuit $C_x$ in parallel with $R_x$. The $Z_2$ and $Z_4$ impedances are pure resistors with either or both being adjustable. The $Z_1$ is balanced by a standard capacitor $C_1$ in parallel with an adjustable resistor $R_1$. The bridge balance is achieved by adjustment of $R_1$ and either $R_2$ or $R_3$. The parallel-resistance-capacitance bridge is found to be most suitable for capacitors with a low-resistance dielectric, hence relatively high leakage currents. At balance:

$$\left( \frac{1}{R_1 + j\omega C_1} \right) R_3 = \left( \frac{1}{R_x + j\omega C_x} \right) R_2$$

(45.28)
Equating real terms gives:

\[ R_x = \frac{R_x R_1}{R_2} \]  \hspace{1cm} (45.29)

and equating imaginary terms gives:

\[ C_x = \frac{C_1 R_1}{R_3} \]  \hspace{1cm} (45.30)

### The Wien Bridge

**Figure 45.16** shows a Wien bridge. This is a special resistance-ratio bridge that permits two capacitances to be compared once all the resistances of the bridge are known. At balance, it can be proven that the unknown resistance and the capacitance are:

\[ R_x = \frac{R_1 \left(1 + \omega^2 R_x^2 C_x^2\right)}{\omega^2 R_1 R_2 C_x^2} \]  \hspace{1cm} (45.31)

and

\[ C_x = \frac{C_1 R_1}{R_3 \left(1 + \omega^2 R_x^2 C_x^2\right)} \]  \hspace{1cm} (45.32)

It can also be shown that:

\[ \omega^2 = \frac{1}{R_1 C_1 R_x C_x} \]  \hspace{1cm} (45.33)
As indicated in Equation 45.33, the Wien bridge has an important application in determining the frequency in $RC$ oscillators. In some cases, capacitors $C_1$ and $C_\alpha$ are made equal and ganged together so that the frequency at which the null occurs varies linearly with capacitance.

**The Schering Bridge**

Figure 45.17 illustrates the configuration of the Schering bridge. This bridge is used for measuring the capacitance, the dissipation factors, and the loss angles. The unknown capacitance is directly proportional to the known capacitance $C_1$. The Schering bridge is frequently used as a high-voltage bridge with a high-voltage capacitor as $C_1$.
Usually, $R_2$ and $R_3$ are fixed and $C_2$ and $C_3$ are made variable. Schering bridges are frequently used in high-voltage applications with high-voltage capacitor $C_j$. They are also used as high-frequency bridges since the use of two variable adjustment capacitors are convenient for precise balancing.

Further Information

Dielectric materials possess relatively few free charge carriers. Most of the charge carriers are bound and cannot participate in conduction. However, these bound charges can be displaced by applying an external electric field. In such cases, the atom or molecule forms an electric dipole that maintains an electric field. Consequently, each volume element of the material behaves as an electric dipole. The dipole field tends to oppose the applied field. Dielectric materials that exhibit nonzero distribution of such bound charge separations are said to be polarized. The volume density of polarization \( \vec{P} \) describes the volume density of those electric dipoles. When a material is linear and isotropic in nature, the polarization density is related to applied electric field intensity, \( \vec{E} \), as follows:

\[
\vec{P} = \varepsilon_0 \chi_e \vec{E}
\]  
(46.1)

where \( \varepsilon_0 = 8.854 \times 10^{-12} \text{ F m}^{-1} \) is the permittivity of free-space and \( \chi_e \) is called the electric susceptibility of the material.

The electric flux density, or displacement, \( \vec{D} \) is defined as follows:

\[
\vec{D} = \varepsilon_0 \vec{E} + \vec{P} = \varepsilon_0 \left(1 + \chi_e\right) \vec{E} = \varepsilon_0 \varepsilon \vec{E} = \varepsilon \vec{E}
\]  
(46.2)

where \( \varepsilon \) is called the permittivity of the material and \( \varepsilon_r \) is its relative permittivity or dielectric constant. Electric flux density is expressed in coulombs per meter (C m\(^{-1}\)).

Equation 46.2 represents a relation between the electric flux density and electric field intensity in frequency domain. It will hold well in time-domain only if the permittivity is independent of frequency. A material is called dispersive if its characteristics are frequency dependent. The product of Equation 46.2 in frequency domain will be replaced by a convolution integral for the time-domain fields.

Assuming that the fields are time-harmonic as \( e^{j\omega t} \), the generalized Ampère's law can be expressed in phasor form as follows:

\[
\nabla \times \vec{H} = \vec{J} + j\omega \vec{D}
\]  
(46.3)
where $H$ is the magnetic field intensity in A m$^{-1}$ and $J'$ is current-source density in A m$^{-2}$. $J$ is the conduction current density in A m$^{-2}$ and the last term represents the displacement current density. $J'$ will be zero for a source-free region.

The conduction current density is related to the electric field intensity through Ohm’s law as follows:

$$\mathbf{J} = \sigma \mathbf{E} \quad (46.4)$$

where $\sigma$ is the conductivity of material in S m$^{-1}$.

From Equations 46.2 through 46.4, one obtains:

$$\nabla \times \mathbf{H} = \mathbf{J}' + \sigma \mathbf{E} + j \omega \epsilon_0 \mathbf{E} \quad (46.5)$$

Conduction current represents the loss of power. There is another source of loss in dielectric materials. When a time-harmonic electric field is applied, the dipoles flip back and forth constantly. Because the charge carriers have finite mass, the field must do work to move them and they might not respond instantaneously. This means that the polarization vector will lag behind the applied electric field. This factor shows up at high frequencies. Therefore, Equation 46.5 is modified as follows:

$$\nabla \times \mathbf{H} = \mathbf{J}' + \sigma \mathbf{E} + \omega \kappa \epsilon_0 \mathbf{E} + j \omega \epsilon_0 \mathbf{E} = \mathbf{J}' + j \omega \left( \epsilon - j \frac{\sigma + \omega \kappa}{\omega} \right) \mathbf{E} = \mathbf{J}' + j \omega \epsilon_0 \mathbf{E} \quad (46.6)$$

The complex relative permittivity of a material is defined as follows:

$$\epsilon_r = \frac{\epsilon'}{\epsilon_0} = \frac{1}{\epsilon_0} \left( \epsilon - j \frac{\sigma + \omega \kappa}{\omega} \right) = \epsilon' - j \kappa'\epsilon = \epsilon' \left(1 - j \tan \delta\right) \quad (46.7)$$

where $\epsilon'$ and $\kappa'$ represent real and imaginary parts of the complex relative permittivity. The imaginary part is zero for a lossless material. The term $\tan \delta$ is called the loss tangent. It represents the tangent of angle between the displacement phasor and total current, as shown in Figure 46.1. Thus, it will be close to zero for a low-loss material.

FIGURE 46.1 A phasor diagram representing displacement and loss currents.
Dispersion characteristics of a large class of materials can be represented by the following empirical equation of Cole-Cole.

\[
\varepsilon'_{\infty} = \varepsilon_\infty - \frac{\varepsilon_\infty - \varepsilon_0}{1+(j\omega \tau)^{1-\alpha}}
\]  (46.8)

where \(\varepsilon_\infty\) and \(\varepsilon_0\) are the relative permittivities of material at infinite and zero frequencies, respectively. \(\omega\) is the signal frequency in radians per second, and \(\tau\) is the characteristic relaxation time in seconds. For \(\alpha\) equal to zero, Equation 46.8 reduces to the Debye equation. Dispersion parameters for a few liquids are given in Table 46.1.

Complex permittivity of a material is determined using lumped circuits at low frequencies, and distributed circuits or free-space reflection and transmission of waves at high frequencies. Capacitance and dissipation factor of a lumped capacitor are measured using a bridge or a resonant circuit. The complex permittivity is calculated from this data. Complex permittivities for some substances are presented in Table 46.2.

At high frequencies, the sample is placed inside a transmission line or a resonant cavity. Propagation constants of the transmission line or resonant frequency and quality factor of the cavity resonator are used to calculate the complex permittivity. Propagation characteristics of electromagnetic waves are influenced by the complex permittivity of that medium. Therefore, a material can be characterized by monitoring the reflected and transmitted wave characteristics as well.

### 46.1 Measurement of Complex Permittivity at Low Frequencies [1, 2]

A parallel-plate capacitor is used to determine the complex permittivity of dielectric sheets. For a separation \(d\) between the plates of area \(A\) in vacuum, the capacitance is given by:

---

© 1999 by CRC Press LLC
where all dimensions are measured in meters. If the two plates have different areas, then the smaller one is used to determine $C_0$. Further, it is assumed that the field distribution is uniform and perpendicular to the plates. Obviously, the fringing fields along the edges do not satisfy this condition. The guard electrodes, as shown in Figure 46.2, are used to ensure that the field distribution is close to the assumed condition. For best results, the width of the guard electrode must be at least $2d$, and the unguarded plate must extend to outer edge of the guard electrode. Further, the gap between the guarded and guard electrodes must be as small as possible.

The radius of guarded electrode is $r_1$, and the inner radius of guard electrode is $r_2$. It is assumed that $R - r_2 \geq 2d$. The area $A$ for this parallel plate capacitor is $\pi r^2$, where $r$ is defined as follows:

$$r = r_1 + \Delta$$

(46.10)

$$\Delta = \frac{1}{2}(r_2 - r_1) - 2d \ln \left( \cosh \frac{\pi (r_2 - r_1)}{4d} \right) = \frac{1}{2}(r_2 - r_1) - 1.4659 \ln \left( \cosh \frac{0.7854 r_2 - r_1}{d} \right)$$

(46.11)

Using the Debye model (i.e., $\alpha = 0$ in Equation 46.8), an equivalent circuit for a dielectric-filled parallel plate capacitor can be drawn as shown in Figure 46.3. If a step voltage $V$ is applied to it, then the current $I$ can be found as follows [2].

$$I = \varepsilon_{_0} C_0 V \delta(t) + \frac{V C_0 (\varepsilon_0 - \varepsilon_{_\infty})}{\tau} \exp \left( -\frac{t}{\tau} \right)$$

(46.12)

where $\tau = RC_0(\varepsilon_0 - \varepsilon_{_\infty})$

The first term in Equation 46.12 represents the charging current of capacitor $\varepsilon_{_0} C_0$ in the upper branch. This current is not measured because it disappears instantaneously. In practice, it needs to be bypassed at short times to protect the detector from overloading or burning. The second term of Equation 46.12 represents charging current of the lower branch of an equivalent circuit. The time constant, $\tau$, is determined following the decay characteristics of this current. Further, the resistance $R$ can be found after
extrapolating this current-time curve to \( t = 0 \). The discharging current characteristics are used to remove \( V \) at \( t = 0 \).

A typical circuit arrangement for the characterization of dielectric materials using a step voltage is shown in Figure 46.4. A standard resistor \( R_1 \) of either 10 G\( \Omega \) or 1 T\( \Omega \) is connected between the guarded electrode and the load resistor \( R_2 \). A feedback circuit is used that forces the voltage drop across \( R_1 \) equal in magnitude but opposite in polarity to that of across \( R_2 \). It works as follows. Suppose that the node between capacitor and \( R_1 \) has a voltage \( V_1 \) with respect to ground. It is amplified but reversed in polarity by the amplifier. Therefore, the current through \( R_1 \) will change. This process continues until the input to the amplifier is zero. The junction between \( R_1 \) and the capacitor will then be at the ground potential. Thus, the meter \( M \) measures voltage across \( R_2 \) that is negative of the voltage across \( R_1 \). Since \( R_1 \) is known, the current through it can be calculated. This current also flows through the sample. \( S_1 \) is used to switch from charging to discharging mode while \( S_2 \) is used to provide a path for surge currents.

Capacitance and dissipation factor of the dielectric-loaded parallel-plate capacitor are used in the medium frequency range to determine the complex permittivity of materials. A substitution method is generally employed in a Schering bridge circuit for this measurement.
In the Schering bridge shown in Figure 46.5, assume that the capacitor \( C_v \) is disconnected for the time being, and the capacitor \( C_s \) contains the dielectric sample. In the case of a lossy dielectric sample, it can be modeled as an ideal capacitor \( C_x \) in series with a resistor \( R_x \). The bridge is balanced by adjusting \( C_d \) and \( R_c \). An analysis of this circuit under the balanced condition produces the following relations.

\[
R_x = \frac{C_d R_x}{C_T} \quad (46.13)
\]

and

\[
C_x = \frac{C_T R_d}{R_x} \quad (46.14)
\]

Quality factor \( Q \) of a series \( RC \) circuit is defined as the tangent of its phase angle, while the inverse of \( Q \) is known as the dissipation factor \( D \). Hence,

\[
Q = \frac{X_x}{R_x} = \frac{1}{\omega C_x R_x} = \frac{1}{D} \quad (46.15)
\]

For a fixed \( R_o \), the capacitor \( C_d \) can be calibrated directly in terms of dissipation factor. Similarly, the resistor \( R_c \) can be used to determine \( C_x \). However, an adjustable resistor limits the frequency range. A substitution method is preferred for precision measurement of \( C_x \) at higher frequencies. In this technique,
a calibrated precision capacitor $C_v$ is connected in parallel with $C_s$ as shown in Figure 46.5 and the bridge is balanced. Assume that the settings of two capacitors at this condition are $C_{d1}$ and $C_{v1}$. The capacitor $C_s$ is then removed and the bridge is balanced again. Let the new settings of these capacitors be $C_{d2}$ and $C_{v2}$, respectively. Equivalent circuit parameters of the dielectric loaded capacitor $C_s$ are then found as follows.

\[
C_s = C_{v2} - C_{v1} \tag{46.16}
\]

\[
D_s = \frac{C_{d2}}{C_s} \delta D \tag{46.17}
\]

where $\delta D = \omega R_s (C_{d1} - C_{d2})$

Complex permittivity of the specimen is calculated from these data as follows:

\[
\varepsilon_r' = \frac{C_s}{C_0} \tag{46.18}
\]

and

\[
\varepsilon_r'' = \frac{C_s D_s}{C_0} \tag{46.19}
\]

Thus far, a series $RC$ circuit equivalent model is used for the dielectric-loaded capacitor. As illustrated in Figure 46.6, an equivalent parallel $RC$ model can also be obtained for it. The following equations can be used to switch back and forth between these two equivalent models.

\[
G_p = \frac{R}{R_s + \frac{1}{\omega C_s^2}} = \frac{1}{R} \left( \frac{1}{1 + Q^2} \right) \tag{46.20}
\]

\[
C_p = \frac{C_s}{1 + (\omega R_s C_s)^2} = \frac{C_s}{1 + D_s^2} \tag{46.21}
\]

\[
R_s = \frac{G_p}{G_p^2 + \omega^2 C_p^2} = \frac{1}{G_p} \left( \frac{1}{1 + Q^2} \right) \tag{46.22}
\]
Proper shielding and grounding arrangements are needed for a reliable measurement, especially at higher frequencies. Grounding and edge capacitances of the sample holder need to be taken into account for improved accuracy. Further, a guard point needs to be obtained that may require balancing in some cases. An inductive-ratio-arm capacitance bridge can be another alternative to consider for such application [1].

### 46.2 Measurement of Complex Permittivity Using Distributed Circuits

Measurement techniques based on the lumped circuits are limited up to the lower end of the VHF band. Characterization of materials at microwave frequencies requires the distributed circuits. A number of techniques have been developed on the basis of wave reflection and transmission characteristics inside a transmission line or in free space. Some other methods employ a resonant cavity that is loaded with the sample. Cavity parameters are measured and the material characteristics are deduced from that. A number of these techniques, described in [3, 4], can be used for a sheet material. These techniques require cutting a piece of sample to be placed inside a transmission line or a cavity. In case of liquid or powder samples, a so-called modified infinite sample method can be used. In this technique, a waveguide termination is filled completely with the sample, as shown in Figure 46.7. Since a tapered termination is embedded in the sample, the wave incident on it will be dissipated with negligible reflection and it will look like the sample is extending to infinity. The impedance at its input port will depend on the electrical properties of filling sample. Its VSWR $S$ and location of first minimum $d$ from the load plane are measured using a slotted line. The complex permittivity of sample is then calculated as follows [5].

\[
\varepsilon' = \left(\frac{\lambda}{\lambda_c}\right)^2 + \left[ \frac{1 - \left(\frac{\lambda}{\lambda_c}\right)^2}{\left[1 + S^2 \tan^2(\beta d)\right]^2} \cdot \frac{S^2 \sec^4(\beta d) - (1 - S^2)^2 \tan^2(\beta d)}{} \right] \times \left[1 + S^2 \tan^2(\beta d)\right] \tag{46.25}
\]

![Figure 46.7](image)
and

\[ \varepsilon'' = \frac{\left[1 - \left(\frac{\lambda}{\lambda_c}\right)^2 \right]}{\left[1 + S^2 \tan^2(\beta d)\right]^2} \times 2S(1 - S^2)^2 \sec^4(\beta d \tan(\beta d)) \]  

(46.26)

where \( \lambda \) = Free-space wavelength

\( \lambda_c \) = Cut-off wavelength for the mode of propagation in empty guide

\( \beta \) = Propagation constant in the feeding guide

It is assumed that the waveguide supports TE_{10} mode only.

**Resonant Cavity Method**

A cavity resonator can be used to determine the complex permittivity of materials at microwave frequencies. If a cavity can be filled completely with the sample, then the following procedure can be used.

Measure the resonant frequency \( f_1 \) and the quality factor \( Q_1 \) of an empty cavity. Next, fill that cavity with the sample material and measure its new resonant frequency \( f_2 \) and quality factor \( Q_2 \). The dielectric parameters of the sample are then calculated from the following formulae [3].

\[ \varepsilon' = \left(1 + \frac{f_1 - f_2}{f_2}\right)^2 \]  

(46.27)

and

\[ \tan \delta = \frac{1}{Q_2} - \frac{1}{Q_1} \sqrt{\frac{f_1}{f_2}} \]  

(46.28)

On the other hand, a cavity perturbation technique will be useful for smaller samples [4]. If the sample is available in a circular cylindrical form, then it may be placed inside a TE_{101} rectangular cavity through the center of its broad face where the electric field is maximum. Its resonant frequency and quality factor with and without sample are then measured. Complex permittivity of sample is calculated as follows.

\[ \varepsilon' = 1 + \frac{1}{2} \frac{f_1 - f_2}{f_2} \frac{V}{v} \]  

(46.29)

and

\[ \varepsilon'' = \frac{V}{4v} \frac{Q_2 - Q_1}{Q_2} \]  

(46.30)

where \( V \) and \( v \) are cavity and sample volumes, respectively.

Similarly, for a small spherical sample of radius \( r \) that is placed in a uniform field at the center of the rectangular cavity, the dielectric parameters are as follows.

\[ \varepsilon' = \frac{abd}{8\pi r^3} \frac{f_1 - f_2}{f_2} \]  

(46.31)
and

$$
\epsilon_r'' = \frac{abd}{16\pi r^3} \left( \frac{Q_2 - Q_3}{Q_2 Q_3} \right) \quad (46.32)
$$

Where \( a, b, \) and \( d \) are the width, height, and length of the rectangular cavity, respectively. For best accuracy in cavity perturbation method, the shift in frequency \( (f_1 - f_2) \) must be very small.

**Free-Space Method for Measurement of Complex Permittivity**

When a plane electromagnetic wave is incident on a dielectric interface, its reflection and transmission depend on the contrast in the dielectric parameters. Many researchers have used it for determining the complex permittivity of dielectric materials placed in free space. An automatic network analyzer and phase-corrected horn antennas can be used for such measurements [6]. The system is calibrated using the TRL (through, reflect, and line) technique. A time-domain gating is used to minimize the error due to multiple reflections. The sample of thickness \( d \) is placed in front of a conducting plane and its reflection coefficient \( S_{11} \) is measured. A theoretical expression for this reflection coefficient is found as follows.

$$
S_{11} = \frac{jZ_d \tan(\beta_d d) - 1}{jZ_d \tan(\beta_d d) + 1} \quad (46.33)
$$

Where:

$$
Z_d = \frac{1}{\sqrt{\epsilon_r'}} \quad (46.34)
$$

$$
\beta_d = \frac{2\pi}{\lambda} \sqrt{\epsilon_r'} \quad (46.35)
$$

\( \lambda \) = Free-space wavelength of electromagnetic signal

Equation 46.33 is solved for \( \epsilon_r' \) after substituting the measured \( S_{11} \). Since it represents a nonlinear relation, an iterative numerical procedure can be used.

**A Nondestructive Method for Measuring the Complex Permittivity of Materials**

Most of the techniques described thus far require cutting and placing a part of sample in the test fixture. Sometimes, it may not be permissible to do so. Further, the dielectric parameters can change in that process. It is especially important in the case of a biological specimen to perform *in vivo* measurements. In one such technique, an open-ended coaxial line is placed in close contact with the sample and its input reflection coefficient is measured using an automatic network analyzer [7, 8]. As recommended by the manufacturers, the network analyzer is calibrated initially using an open-circuit, a short-circuit, and a matched load. The reference plane is then moved to the measuring end of the coaxial line using a short-circuit.

Assume that \( a \) and \( b \) are inner and outer radii of the coaxial line, respectively. \( \omega \) is the angular frequency; \( \mu_0 \) and \( \epsilon_0 \) are the permeability and permittivity of the free space, respectively, \( k = \omega \sqrt{\mu_0 \epsilon_0} \) is the wavenumber in material medium. Admittance of the coaxial aperture in contact with material medium is as follows.
where \( E_r(r',0) \) is radial electric field intensity over the aperture. It is evaluated from the following integral equation.

\[
\frac{1}{\pi \rho} + j \alpha e \varepsilon_o \int_a^b E_r(p',0) K_i(p, p') dp' = \frac{j \alpha e \varepsilon_o}{\pi} \int_a^b E_r(p',0) p' dp' \cos(\phi') \frac{\exp(-jkr)}{r} \, d\phi' \quad \text{(46.37)}
\]

Where:

\[
r = \sqrt{\rho^2 + \rho'^2 - 2 \rho \rho' \cos(\phi') } \quad \text{(46.38)}
\]

\[
K_i(p, p') = \sum_{n=0}^{\infty} \frac{\Phi_n(p) \Phi_n(p')}{A_n^2} \quad \text{(46.39)}
\]

\[
\Phi_n = Y_0(\gamma_n a) J_1(\gamma_n p) - J_0(\gamma_n a) Y_1(\gamma_n p) \quad \text{(46.40)}
\]

\[
\beta_n = \begin{cases} \sqrt{k_i^2 - \gamma_n^2} & \text{if } k_i > \gamma_n \\ -j \sqrt{\gamma_n^2 - k_i^2} & \text{if } k_i < \gamma_n \end{cases} \quad \text{(46.41)}
\]

\[
A_n^2 = \frac{2}{\pi^2 \gamma_n^2} \left[ \frac{J_1^2(\gamma_n a)}{J_0^2(\gamma_n b)} - 1 \right] \quad \text{if } n > 0 \quad A_0^2 = \ln \left( \frac{b}{a} \right) \quad \text{(46.42)}
\]

The eigenvalues \( \gamma_n \) are solutions to the following characteristic equation:

\[
J_0(\gamma_n b) Y_0(\gamma_n a) = J_1(\gamma_n a) Y_0(\gamma_n b) \quad \text{(46.43)}
\]

\( J_n \) and \( Y_n \) are Bessel functions of the first and second kind of order \( n \), respectively. \( \varepsilon_r \) is the dielectric constant of the insulator and \( k_i \) is wavenumber inside the coaxial line.

Equation 46.37 is solved numerically using the method of moments. A numerical root-finding procedure, such as the Muller’s method, is used to solve Equation 46.36 for the complex wavenumber \( k \). Complex permittivity, in turn, is determined from the following relation.

\[
\varepsilon_r^* = -\frac{k_i^2}{\omega \mu \varepsilon_0} \quad \text{(46.44)}
\]
Defining Terms

**Electric dipole**: A pair of equal and opposite electric charges separated by a small distance.

**Isotropic material**: A material in which the electrical polarization has the same direction as the applied electric field.

**Electric polarization density**: The average electric dipole moment per unit volume.

**Electric susceptibility**: A dimensionless parameter that relates the polarization density in a material with electric field intensity.

**Electric flux density**: A fundamental electric field quantity that is related to volume density of free charges. It is also known as the electric displacement.

**Time domain field**: A field expressed as a function of time. It is a real function that is dependent on time and space coordinates.

**Frequency domain field**: A phasor quantity (a complex function in general) that depends on space coordinates. The time dependency is assumed to be sinusoidal.

**Displacement current density**: It represents the time rate of change of electric flux density.

**Conduction current density**: Current per unit area caused by conduction of charge carriers.

**Dielectric constant**: A dimensionless constant that represents the permittivity of a material relative to the permittivity of free space.

**Loss tangent**: A ratio of the imaginary part to the real part of the complex permittivity of a material.

**Relaxation time**: It represents the time taken by a charge placed inside a material volume to decay to about 37% of its initial value.

**Quality factor**: A dimensionless quantity that represents the time average energy stored in an electrical circuit relative to energy dissipated in one period.

**Dissipation factor**: It is the inverse of the quality factor.

**Voltage standing wave ratio (VSWR)**: Defined as a ratio of maximum voltage to the minimum voltage on a transmission line.

**Reflection coefficient**: Defined as a ratio of reflected phasor voltage to that of incident phasor voltage at a point in the circuit.

Electric Field Strength

David A. Hill  
*National Institute of Standards and Technology*

Motohisa Kanda  
*National Institute of Standards and Technology*

**Electric field strength** is defined as the ratio of the force on a positive test charge at rest to the magnitude of the test charge in the limit as the magnitude of the test charge approaches zero. The units of electric field strength are volts per meter (V m\(^{-1}\)). Electric charges and currents are sources of electric and magnetic fields, and Maxwell’s equations \([1]\) provide the mathematical relationships between electromagnetic (EM) fields and sources.

The electric field at a point in space is a vector defined by components along three orthogonal axes. For example, in a rectangular coordinate system, the electric field \(\vec{E}\) can be written as:

\[
\vec{E} = \hat{x}E_x + \hat{y}E_y + \hat{z}E_z
\]

(47.1)

where \(\hat{x}, \hat{y}\), and \(\hat{z}\) are unit vectors and \(E_x, E_y, \text{ and } E_z\) are scalar components. For electrostatic fields, the components are real scalars that are independent of time. For steady-state, time-harmonic fields, the components are complex phasors that represent magnitude and phase. The time dependence, \(e^{j\omega t}\), is suppressed.

**47.1 Electrostatic Fields**

Electrostatic fields are present throughout the atmosphere, and there are strong electrostatic fields near high-voltage dc power lines. The commonly used electrostatic field meters generate an ac signal by periodic conductor motion (either rotation or vibration). This ac signal is proportional to the electric field strength, and field meter calibration is performed in a known electrostatic field.

Field Mills

Field mills (also called generating voltmeters) determine electric field strength by measuring modulated, capacitively induced charges or currents on metal electrodes. Two types of field mills — the shutter type and the cylindrical type — are described in the technical literature [2]. The shutter type is more common; a simplified version is shown in Figure 47.1. The sensing electrode is periodically exposed to and shielded from the electric field by a grounded, rotating shutter. The charge $q_i$ induced on the sensing electrode and the current $i$, between the sensing electrode and ground are both proportional to the electric field strength $E$ normal to the electrode:

$$q_i(t) = \varepsilon_0 E a_i(t) \quad \text{and} \quad i(t) = \varepsilon_0 E \frac{da_i(t)}{dt} \quad (47.2)$$

where $\varepsilon_0$ is the permittivity of free space [1] and $a_i(t)$ is the effective exposed area of the sensing electrode at time $t$.

Thus, the field strength can be determined by measuring the induced charge or current (or voltage across the impedance $Z$). If the induced signal is rectified by a phase-sensitive detector (relative to the shutter motion), the dc output signal will indicate both the polarity and magnitude of the electric field [3].

**FIGURE 47.1** Shutter-type electric field mill for measurement of the polarity and magnitude of an electrostatic field.
Shutter-type field mills are typically operated at the ground or at a ground plane, but a cylindrical field mill can be used to measure the electric field at points removed from a ground plane. A cylindrical field mill consists of two half-cylinder sensing electrodes as shown in Figure 47.2. Charges induced on the two sensing electrodes are varied periodically by rotating the sensing electrodes about the cylinder axis at a constant angular frequency $\omega_c$. The charge $q_c$ induced on a half-cylinder of length $L$ and the current $i_c$ between the half-cylinders are given by:

$$q_c = 4\epsilon_0 r_c L E \sin \omega_c t \quad \text{and} \quad i_c = 4\epsilon_0 r_c L E \omega_c \cos \omega_c t$$

(47.3)

where $r_c$ is the cylinder radius. Equation 47.3 is based on the two-dimensional solution for a conducting cylinder in an electric field and neglects end effects for finite $L$. Equation 47.3 shows that the electric field strength $E$ can be determined from a measurement of the induced charge or current.

A third type of electric field meter uses a vibrating plate [4] to generate an ac signal that is proportional to the electric field strength. With any type of electric field strength meter, the observer should be at a sufficient distance from the measurement location to avoid perturbing the electric field.

**Calibration Field**

A known uniform field for meter calibration can be produced between a pair of parallel plates [2]. If a potential difference $V$ is applied between a pair of plates with a separation $d_p$, the field strength away from the plate edges is $V/d_p$. The plate dimensions should be much larger than $d_p$ to provide an adequate region of uniform field. Also, $d_p$ should be much larger than the field meter dimensions so that the charge distribution on the plates is not disturbed. The parallel plates can be metal sheets or tightly stretched metal screens.

The field meter should be located in the type of environment in which it will be used. Shutter-type field mills that are intended to be located at a ground plane should be located at one of the plates. Cylindrical field mills that are not intended to be used at a ground plane should be located in the center of the region between the plates.

For simplicity, only field mills and calibration in the absence of space charge were mentioned. However, near power lines or in the upper atmosphere [5], the effects of space charge can be significant and require modifications in field mill design. A field mill for use in a space charge region and a calibration system with space charge are described in [6].
47.2 ELF and ULF Electric Fields

In this section, measurement techniques for extremely low frequency (ELF, 3 Hz to 3 kHz) and ultralow frequency (ULF, below 3 Hz) electric fields are considered. Natural ELF fields are produced by thunderstorms, and natural ULF fields are produced by micropulsations in the earth’s magnetic field [7]. Geophysicists make use of these natural fields in the magnetotelluric method for remote sensing of the Earth’s crust [8]. AC power lines are dominant sources of fields at 50 Hz or 60 Hz and their harmonics.

An AC electric field strength meter [9] includes two essential parts: (1) an antenna and (2) a detector (receiver). Other possible features are a transmission line or optical link, frequency-selective circuits, amplifying and attenuating circuits, an indicating device, and a nonconducting handle. The antenna characteristics can be calculated for simple geometries or determined by calibration. For example, linear antennas are often characterized by their effective length $L_{\text{eff}}$ [10], which determines the open-circuit voltage $V_{\text{oc}}$ induced at the antenna terminals:

$$V_{\text{oc}} = L_{\text{eff}} E_{\text{inc}}$$  \hspace{1cm} (47.4)

where $E_{\text{inc}}$ is the component of the incident electric field parallel to the axis of the linear antenna. The detector could respond to the terminal voltage or current or to the power delivered to the load.

Natural Horizontal Electric Field at the Earth’s Surface

Magnetotelluric sounding of the Earth’s crust requires measurement of the horizontal electric and magnetic fields at the Earth’s surface [8]. The magnetic field is measured with a horizontal axis loop, and the electric field is measured with a horizontal wire antenna as shown in Figure 47.3. The antenna wire is insulated since it lies on the ground, but it is grounded at its end points. Nonpolarizing grounding electrodes should be used to avoid polarization potentials between the electrodes and the ground.

Since the natural electric field strength to be measured is on the order of 1 $\mu$V m$^{-1}$, the antenna length $L_h$ needs to be on the order of 1 km to produce a measurable voltage. Since the effective length of a grounded antenna is equal to the physical length ($L_{\text{eff}} = L_h$), the horizontal component $E_h$ of the electric field parallel to the antenna is equal to the open-circuit voltage divided by the antenna length:

$$E_h = V_{\text{oc}} / L_h$$  \hspace{1cm} (47.5)

The frequencies used in typical magnetotelluric sounding range from approximately 0.1 mHz to 10 Hz. If both horizontal components of the electric field are needed, a second orthogonal antenna is required.
Free-Body Electric Field Meters

ELF electric fields in residential and industrial settings are most conveniently measured with free-body field meters [11, 12], which measure the steady-state current or charge oscillating between two halves of a conducting body in free space. (Ground reference meters [13] are also available for measuring the electric field normal to the ground or some other conducting surface.) Geometries for free-body electric field meters are shown in Figure 47.4. Commercial field meters are usually rectangular in shape, and typical dimensions are on the order of 10 cm. A large dynamic range (1 V m$^{-1}$ to 30 kV m$^{-1}$) is required to cover the various field sources (ac power lines, video display terminals, mass transportation systems, etc.) of interest. (Electro-optic field meters with less sensitivity are described in [12].) A long, nonconducting handle is normally attached perpendicular to the field-meter axis for use in measurement surveys.

The charge $Q$ on half of the field meter is proportional to the incident electric field $E$ along the meter axis:

$$Q = A \varepsilon_0 E$$  \hspace{1cm} (47.6)

where $\varepsilon_0$ is the permittivity of free space [1] and $A$ is a constant proportional to the surface area. For the spherical geometry in Figure 47.4(a), $A = 3\pi a^2$, where $a$ is the sphere's radius. Since the current $I$ between the two halves is equal to the time derivative of the charge, for time-harmonic fields it can be written:

$$I = j\omega A \varepsilon_0 E$$  \hspace{1cm} (47.7)

This allows $E$ to be determined from the measured current. For commercial field meters that are not spherical, the constant $A$ needs to be determined by calibration. A known calibration field can be generated between a pair of parallel plates where the plates are sufficiently large compared to the separation to produce a uniform field with small edge effects. This technique produces a well-characterized field with an uncertainty less than 0.5% [11]. However, the presence of harmonic frequencies can cause less accurate meter readings in field surveys.

47.3 Radio-Frequency and Microwave Techniques

Dipole Antennas

A thin, linear dipole antenna of length $L$ is shown in Figure 47.5. Its effective length is approximately [10]:

---

FIGURE 47.4 Electric field meters for measurement of the axial component of the electric field: (a) spherical geometry and (b) rectangular geometry.
where $\lambda$ is the free-space wavelength. Resonant half-wave dipoles ($L = \lambda/2$) have an effective length of $L_{\text{eff}} = 2L/\pi$ and are of convenient length for frequencies from 30 to 1000 MHz. The physical length of a dipole at resonance is actually slightly shorter than $\lambda/2$ to account for the effect of a finite length-to-diameter ratio. Resonant dipoles are used as standard receiving antennas to establish a known standard field in the standard antenna method [9]. Commercial antennas and field meters are calibrated in such standard fields.

For $L < \lambda/2$, Equation 47.8 must be used to determine $L_{\text{eff}}$. For very short dipoles ($L/\lambda \ll 1$), the current distribution is approximately linear, and the effective length is approximately one half the physical length ($L_{\text{eff}} = L/2$). Short dipoles are frequently used as electric field probes.

### Aperture Antennas

Aperture antennas are commonly used for receiving and transmitting at microwave frequencies (above 1 GHz). As receiving antennas, they are conveniently characterized by their on-axis gain $g$ or effective area $A_{\text{eff}}$. Effective area is defined as the ratio of the received power $P_r$ to the incident power density $S_{\text{inc}}$ and can also be written in terms of the gain [9]:

$$A_{\text{eff}} = \frac{P_r}{S_{\text{inc}}} = \frac{g\lambda^2}{4\pi} \quad (47.9)$$

Equation 47.9 applies to the case where the incident field is polarization-matched to the receiving antenna. The incident power density in a plane wave is $S_{\text{inc}} = E^2/\eta_0$, where $E$ is the rms electric field strength and $\eta_0$ is the impedance of free space ($\approx 377 \ \Omega$). Thus, the electric field strength can be determined from the received power:

$$E = \sqrt{\frac{P_r \eta_0}{A_{\text{eff}}}} = \frac{\lambda^{-1}}{4\pi \eta_0} \frac{P_r}{g} \quad (47.10)$$

In general, the gain can be measured using the two-antenna method [9]. For a pyramidal horn antenna as shown in Figure 47.6, the gain can be calculated accurately from [14]:

$$g = \frac{32 \ ab}{\pi \lambda^2} \frac{R_e R_i}{\eta^2} \quad (47.11)$$

---

**FIGURE 47.5** Dipole antenna for measurement of the axial component of the electric field.

$$L_{\text{eff}} = \frac{\lambda}{\pi} \tan \left( \frac{\pi L}{2\lambda} \right) \quad (47.8)$$
where $R_E$ and $R_H$ are gain reduction factors due to the $E$ and $H$ plane flare of the horn. The gain reduction factors are

$$R_E = \frac{C^2(w) + S^2(w)}{w^2} \quad \text{and} \quad R_H = \frac{\pi^2\left\{C(u) - C(v)\right\}^2 + \left\{S(u) - S(v)\right\}^2}{4(u-v)^2}, \quad (47.12)$$

Where:

$$w = \frac{b}{\sqrt{2}\lambda E} \quad \text{and} \quad u = \frac{\sqrt{\lambda H/2}}{a} \pm \frac{a}{\sqrt{2}\lambda H}$$

The Fresnel integrals $C$ and $S$ are defined as [15]:

$$C(w) = \int_0^w \cos\left(\frac{\pi t^2}{2}\right) \, dt \quad \text{and} \quad S(w) = \int_0^w \sin\left(\frac{\pi t^2}{2}\right) \, dt \quad (47.13)$$

Well-characterized aperture antennas are also used to generate standard fields [16] for calibrating commercial antennas and field strength meters. This method of calibration is called the standard field method [9]. The electric field strength $E$ at a distance $d$ from the transmitting antenna is:

$$E = \sqrt{\frac{n_0 P_{\text{del}}}{(4\pi)^2}} / d, \quad (47.14)$$
where $P_{\text{del}}$ is the net power delivered to the transmitting antenna and is typically measured with a directional coupler \[16\]. The gain $g$ for a pyramidal horn can be calculated from Equation 47.11. The National Institute of Standards and Technology (NIST) uses rectangular open-ended waveguides from 200 MHz to 500 MHz and a series of pyramidal horns from 500 MHz to 40 GHz to generate standard fields in an anechoic chamber \[16\]. The uncertainty of the field strength is less than 1 dB over the entire frequency range of 200 MHz to 40 GHz.

**47.4 Three-Loop Antenna System**

Electronic equipment can emit unintentional electromagnetic radiation that can interfere with other electronic equipment. If the radiating source is electrically small (as is a video display terminal), then it can be characterized by equivalent electric and magnetic dipole moments. The three-loop antenna system (TLAS), shown in Figure 47.7, consists of three orthogonal loop antennas that are terminated at diametrically opposite points. The unique feature of loop antennas with double terminations \[17\] is that they can measure both electric and magnetic fields. For electromagnetic interference (EMI) applications, a device under test (DUT) is placed at the center of the TLAS. On the basis of six terminal measurements, the TLAS determines three equivalent electric dipole components and three equivalent magnetic dipole moments of the DUT and hence its radiation characteristics.

Here, the theory \[18\] is summarized for one of the three loops. The DUT in Figure 47.7 is replaced by an electric dipole moment $\vec{m}_e$ and a magnetic dipole moment $\vec{m}_m$, both located at the origin of the coordinate system. The dipole moments can be written in terms of their rectangular components:

\[
\vec{m}_e = \hat{x}m_{ex} + \hat{y}m_{ey} + \hat{z}m_{ez} \quad \text{and} \quad \vec{m}_m = \hat{x}m_{mx} + \hat{y}m_{my} + \hat{z}m_{mz}
\]  

(47.15)

The loop in the $xy$ plane has radius $r_c$ and has impedance loads $Z_{xy}$ located at the intersections with the $x$ axis ($\phi = 0, \pi$).

The solution for the current induced in the loop is based on Fourier series analysis \[19\]. The incident azimuthal electric field $E_\psi(\phi)$ tangent to the loop is:

\[ \hat{x} \]
Where: 

\[ A_n = m_{m_n} G_m \]
\[ A_\phi = m_{m_\phi} G_\phi \]
\[ B_\phi = -m_{m_\phi} G_\phi \]
\[ G_m = \frac{\eta_0}{4\pi} \left( \frac{k^2}{r_0} - \frac{j k}{r_0^3} \right) e^{-\beta r_0} \]
\[ G_\phi = \frac{-\eta_0}{4\pi} \left( \frac{k}{r_0} + \frac{1}{r_0^3} + \frac{1}{j k r_0^2} \right) e^{-\beta r_0} \]

and \( k = 2\pi/\lambda \) is the free-space wavenumber. An approximate solution [17] for the loop current \( I(\phi) \) yields the following results for the load currents \( I(0) \) and \( I(\pi) \):

\[ I(0) = 2\pi r_0 \left( \frac{m_{m_\phi} G_m Y_0}{1 + 2 Y_0 Z_{xy}} + \frac{m_{m_\phi} G_\phi Y_1}{1 + 2 Y_1 Z_{xy}} \right) \]
\[ I(\pi) = 2\pi r_0 \left( \frac{m_{m_\phi} G_m Y_0}{1 + 2 Y_0 Z_{xy}} - \frac{m_{m_\phi} G_\phi Y_1}{1 + 2 Y_1 Z_{xy}} \right) \]

(47.17)

where \( Y_0 \) and \( Y_1 \) are the admittances for the constant and \( \cos \phi \) currents [17].

One can solve Equation 47.17 for the magnetic and electric dipole components:

\[ m_{m_\phi} = \frac{I(0)(1 + 2 Y_0 Z_{xy})}{2\pi r_0 G_m Y_0} \]
\[ m_{m_\phi} = \frac{I(\pi)(1 + 2 Y_0 Z_{xy})}{2\pi r_0 G_\phi Y_1} \]

(47.18)

Where:

\[ I_c = \left[ I(0) + I(\pi) \right]/2 \]
\[ I_\Delta = \left[ I(0) - I(\pi) \right]/2 \]

Thus, the sum current \( I_c \) can be used to measure the magnetic dipole moment, and the difference current \( I_\Delta \) can be used to measure the electric dipole moment. The four remaining dipole components can be obtained in an analogous manner. The loop in the \( xy \) plane can be used to measure \( m_{m_\phi} \) and \( m_{m_\phi} \), and the loop in the \( yz \) plane can be used to measure \( m_{m_\phi} \) and \( m_{m_\phi} \).

The total power \( P_T \) radiated by the source can be written in terms of the magnitudes of the six dipole components:

\[ P_T = \frac{2\pi \eta_0}{3\lambda^2} \left[ |m_{m_\phi}|^2 + |m_{m_\phi}|^2 + |m_{m_\phi}|^2 + k^2 \left( |m_{m_\phi}|^2 + |m_{m_\phi}|^2 + |m_{m_\phi}|^2 \right) \right] \]

(47.19)

The expression for the power pattern is more complicated and involves the amplitudes and phases of the dipole moments [20]. The TLAS has been constructed with 1-m diameter loops and successfully
tested from 3 kHz to 100 MHz [21]. It is currently being used to measure radiation from video display terminals and other inadvertent radiators.

## 47.5 Broadband Dipole Antennas

The EM environment continues to grow more severe and more complex as the number of radiating sources increases. Broadband antennas are used to characterize the EM environment over a wide frequency range. For electric-field measurements, electrically short dipole antennas with a high capacitive input impedance are used with a capacitive load, such as a field-effect transistor (FET). The transfer function \( S \) of frequency \( f \) is defined as the ratio of the output voltage \( V \) of the antenna to the incident electric field \( E_i \) [22]:

\[
S(f) = \frac{V_i(f)}{E_i(f)} = \frac{h\alpha/2}{1 + C/C_a}
\]  

(47.20)

Where:

\[
C_a = \frac{4\pi h}{\eta_b \Omega_a - 2 - \ln 4}
\]

\[
\Omega_a = 2 \ln \left( \frac{2h}{r_a} \right)
\]

\[
\alpha = \frac{\Omega_a - 1}{\Omega_a - 2 + \ln 4}
\]

\[r_a = \text{Antenna radius}\]
\[C = \text{Load capacitance}\]
\[C_a = \text{Antenna capacitance}\]
\[h = \text{Half the physical length of the dipole antenna, as shown in Figure 47.5}\]
\[c = \text{Free-space speed of light}\]
\[\Omega_a = \text{Antenna thickness factor}\]

Since the input impedance of an electrically short dipole is predominantly a capacitive reactance, a very broadband frequency response can be achieved with a high-impedance capacitive load. However, given the present state of the art, it is not possible to build a balanced, high-input impedance FET with high common-mode rejection above 400 MHz. For this reason, it is more common practice to use a high-frequency, beam-lead Schottky-barrier diode with a very small junction capacitance (less than 0.1 pF) and very high junction resistance (greater than several MΩ) for frequencies above 400 MHz.

The relationship between the time-dependent diode current \( i_d(t) \) and voltage \( v_d(t) \) is

\[
i_d(t) = I_o \left[ e^{\alpha_d v(t)} - 1 \right]
\]

(47.21)

where \( I_o \) and \( \alpha_d \) are constants of the diode. For very small incident fields \( E_i(t) \), the output detected dc voltage \( v_o \) is:

\[
v_o = -\frac{h^2}{2 \alpha_d} \left\langle \hat{\psi}^2 \right\rangle
\]

(47.22)
\[ v_i = E_i L_e \]

Where:

\[ \dot{v}_i(t) = v_i(t) - \langle v_i \rangle \]

\[ b_d = \frac{C_a \alpha_d}{C_a + C_d} \]

- \( C_a \) = Dipole capacitance
- \( C_d \) = Diode capacitance
- \( L_e \) = Effective length of the dipole antenna
- \( \langle \rangle \) Indicates time average

Thus, the dc detected voltage is frequency independent and is directly proportional to the average of \((E_i - \langle E_i \rangle)^2\).

For large incident fields \( E_i(t) \), the output detected dc voltage is:

\[ v_0 = -\frac{b_d v_i}{\alpha_d} \]

(47.23)

where \( v_i \) is the peak value of \( v_i(t) \). Consequently, for a large incident field, \( v_0 \) is also frequency independent and is directly proportional to the peak field.

Conventional dipole antennas support a standing-wave current distribution; thus, the useful frequency range of this kind of dipole is usually limited by its natural resonant frequency. In order to suppress this resonance, a resistively loaded dipole (traveling-wave dipole) has been developed. If the internal impedance per unit length \( Z_l(z) \) as function of the axial coordinate \( z \) (measured from the center of the dipole) has the form:

\[ Z_l(z) = \frac{60 \psi}{h - z} \]

(47.24)

then the current distribution \( I_z(z) \) along the dipole is that of a traveling wave. Its form is

\[ I_z(z) = \frac{V_0}{60 \psi (1 - j/kh)} \left[ 1 - \frac{h}{2} e^{-jkh} \right] \]

(47.25)

where \( 2h \) = Total physical length of the dipole
- \( V_0 \) = Driving voltage

\[ \psi = 2 \left[ \sinh^{-1} \frac{h}{a_d} - C \left( 2k a_d, 2kh \right) - jS \left( 2k a_d, 2kh \right) \right] + \frac{j}{kh} \left( 1 - e^{-jkh} \right) \]

(47.26)

\( C(x,y) \) and \( S(x,y) \) = Generalized cosine and sine integrals
- \( a_d \) = Dipole radius

This type of resistively tapered dipole has a fairly flat frequency response from 100 kHz to 18 GHz [23].
Defining Terms

**Electric field strength:** The ratio of the force on a positive test charge to the magnitude of the test charge in the limit as the magnitude of the test charge approaches zero.

**Electrostatic field:** An electric field that does not vary with time.

**Field mill:** A device used to measure an electrostatic field.

**Antenna:** A device designed to radiate or to receive time-varying electromagnetic waves.

**Microwaves:** Electromagnetic waves at frequencies above 1 GHz.

**Power density:** The time average of the Poynting vector.

**Aperture antenna:** An antenna that radiates or receives electromagnetic waves through an open area.

**Dipole antenna:** A straight wire antenna with a center feed used for reception or radiation of electromagnetic waves.

References

Magnetic field strength is measured using a variety of different technologies. Each technique has unique properties that make it more suitable for particular applications. These applications can range from simply sensing the presence or change in the field to the precise measurements of a magnetic field’s scalar and vector properties. A very good and exhaustive fundamental description of both mechanical and electrical means for sensing magnetic fields can be found in Lion [1]. Less detailed but more up-to-date surveys of magnetic sensor technologies can be found in [2, 3]. It is not possible to adequately describe all of these technologies in the space available in a Handbook. This chapter concentrates on sensors that are commonly used in magnetic field measuring instruments.

As shown in Figure 48.1, magnetic field sensors can be divided into vector component and scalar magnitude types. The vector types can be further divided into sensors that are used to measure low fields (<1 mT) and high fields (>1 mT). Instruments that measure low fields are commonly called magnetometers. High-field instruments are usually called gaussmeters.

The induction coil and fluxgate magnetometers are the most widely used vector measuring instruments. They are rugged, reliable, and relatively less expensive than the other low-field vector measuring instruments. The fiber optic magnetometer is the most recently developed low-field instrument. Although it currently has about the same sensitivity as a fluxgate magnetometer, its potential for better performance is large. The optical fiber magnetometer has not yet left the laboratory, but work on making it more rugged and field worthy is under way. The superconducting quantum interference device (SQUID) magnetometers are the most sensitive of all magnetic field measuring instruments. These sensors operate at temperatures near absolute zero and require special thermal control systems. This makes the SQUID-based magnetometer more expensive, less rugged, and less reliable.

The Hall effect device is the oldest and most common high-field vector sensor used in gaussmeters. It is especially useful for measuring extremely high fields (>1 T). The magnetoresistive sensors cover the middle ground between the low- and high-field sensors. Anisotropic magnetoresistors (AMR) are currently being used in many applications, including magnetometers. The recent discovery of the giant
magnetoresistive (GMR) effect, with its tenfold improvement in sensitivity, promises to be a good competitor for the traditional fluxgate magnetometer in medium-sensitivity applications.

The proton (nuclear) precession magnetometer is the most popular instrument for measuring the scalar magnetic field strength. Its major applications are in geological exploration and aerial mapping of the geomagnetic field. Since its operating principle is based on fundamental atomic constants, it is also used as the primary standard for calibrating magnetometers. The proton precession magnetometer has a very low sampling rate, on the order of 1 to 3 samples per second, so it cannot measure fast changes in the magnetic field. The optically pumped magnetometer operates at a higher sampling rate and is capable of higher sensitivities than the proton precession magnetometer, but it is more expensive and not as rugged and reliable.

Table 48.1 lists various magnetic field strength instruments and their characteristics.

### 48.1 Magnetic Field Fundamentals

An understanding of the nature of magnetic fields is necessary in order to understand the techniques used for measuring magnetic field strength. The most familiar source of a magnetic field is the bar...
magnet. The field it produces is shown in Figure 48.2. Magnetic field is a vector quantity; that is, it has both a magnitude and a direction. The field of a bar magnet or any other magnetized object, when measured at a distance much greater than its longest dimension, is described by Equation 48.1:

$$\vec{H} = \frac{3(\vec{m} \times \hat{r})\hat{r} - \vec{m}}{r^3}$$ \hspace{1cm} (48.1)

where $\hat{r}$ is a unit vector along $r$, $r$ is the distance between the magnetic field source and the measurement point, and $\vec{m}$ is called the magnetic dipole moment. The derivation of this equation can be found in many textbooks on electromagnetics. This is a very convenient equation for estimating the field produced by many magnetized objects.

The strength or intensity of a magnetized object depends on the density of its volume-distributed moments. This intensity is called its magnetization $\vec{M}$, which is defined as the moments per unit volume:

$$\vec{M} = \frac{\vec{m}}{\text{volume}}$$ \hspace{1cm} (48.2)

Like magnetic field, magnetization is a vector quantity. Magnetization is a material property that can arise from internal magnetic sources as well as be induced by an external magnetic field.

There is a third magnetic vector $\vec{B}$ called magnetic induction or flux density. In free space, magnetic field and magnetic induction are proportional to one another by a constant factor $\mu_0$.

$$\vec{B} = \mu_0 \vec{H}$$ \hspace{1cm} (48.3)

Things are different in matter. Equation 48.4 describes the relationship among the magnetic field, magnetic induction, and magnetization vectors in matter:

$$\vec{B} = \mu_0 \left( \vec{H} + \vec{M} \right)$$ \hspace{1cm} (48.4)
In this case, the magnetic induction and the magnetic field vectors do not necessarily have the same direction. Some materials have anisotropic magnetic properties that make these two vectors point in different directions. The magnetization vector can consist of permanent and induced magnetization components. The permanent magnetization vector does not depend on the presence of an external field. The induced magnetization vector does depend on an external magnetic field and only exists while the inducing field is present.

Magnetic materials can be loosely classified as magnetically “soft” or magnetically “hard.” In a magnetically hard material, the permanent magnetization component dominates (a magnet is an example). Magnetization in a soft magnetic material is largely induced and is described by the following equation:

\[ \vec{M} = \chi \vec{H} \]  

(48.5)

where \( \chi \) is called the material’s magnetic susceptibility. In an isotropic material (magnetic properties are not direction dependent), \( \chi \) is a scalar quantity, and the magnetization and field vectors are proportional and aligned. In anisotropic material (magnetic properties depend on direction), \( \chi \) is a tensor represented by a \( 3 \times 3 \) matrix; therefore, the magnetization vector magnitude and direction depend on the direction and strength of the inducing field. As a result, the magnetization vector will not always align with the magnetization inducing field vectors. Equation 48.5 can be modified for magnetically “soft” material to the following:

\[ \vec{B} = \mu_o \left( 1 + \chi \right) \vec{H} = \mu_o \mu \vec{H} \]  

(48.6)

where \( \mu \) is called the relative permeability of the material.

A magnetized object with a magnetic moment \( \vec{m} \) will experience torque \( \vec{T} \) in the presence of a uniform magnetic field \( \vec{H} \). Equation 48.7 expresses this relationship.

\[ \vec{T} = \vec{m} \times \vec{H} \]  

(48.7)

Torque is the cross-product of the magnetic moment and field vectors. The magnitude equation is:

\[ T = mH \sin \theta \]  

(48.8)

where \( \theta \) is the angle between the direction of \( \vec{m} \) and \( \vec{H} \).

There is an intimate relationship between electric and magnetic fields. Oersted discovered that passing a current through a wire near a compass causes the compass needle to rotate. The compass was the first magnetic field strength sensor. Faraday found that he could produce an electric voltage at the terminals of a loop of wire if he moved a magnet near it. This led to the induction or search coil sensor.

Magnetic fields are produced by the flow of electric charge (i.e., electric currents). In effect, a magnetic field is a velocity-transformed electric field (through a Lorentz transformation). Current flowing through a straight wire, a loop of wire, or a solenoid will also produce a magnetic field as illustrated in Figure 48.3.

Units are always a problem when dealing with magnetic fields. The Gaussian cgs (centimeter, gram, and second) system of units was favored for many years. Since \( \mu_0 = 1 \) in the cgs system, magnetic field and flux density have the same numeric value in air, and their units (oersted for field and gauss for flux density) are often indiscriminately interchanged. This has led to great confusion. The cgs system has now been replaced by the International System of Units (SI). The SI system uses, among others, the meter (m), kilogram (kg), second (s) and ampere (A) as the fundamental units. Payne [4] gives a very good explanation of the differences between these systems of units as they relate to magnetic fields. Table 48.2 summarizes the relationships between the two systems of units.

The SI system of units is used throughout this chapter.
The induction or search coil, which is one of the simplest magnetic field sensing devices, is based on Faraday’s law. This law states that if a loop of wire is subjected to a changing magnetic flux, \( \phi \), through the area enclosed by the loop, then a voltage will be induced in the loop that is proportional to the rate of change of the flux:

\[
e(t) = -\frac{d\phi}{dt}
\]  

\[\text{(48.9)}\]

**48.2 Low-Field Vector Magnetometers**

**The Induction Coil Magnetometer**

The induction or search coil, which is one of the simplest magnetic field sensing devices, is based on Faraday’s law. This law states that if a loop of wire is subjected to a changing magnetic flux, \( \phi \), through the area enclosed by the loop, then a voltage will be induced in the loop that is proportional to the rate of change of the flux:

\[
e(t) = -\frac{d\phi}{dt}
\]  

\[\text{(48.9)}\]
Since magnetic induction \( \mathbf{B} \) is flux density, then a loop with cross-sectional area \( \mathbf{A} \) will have a terminal voltage:

\[
e(t) = -\frac{d(\mathbf{B} \cdot \mathbf{A})}{dt}
\]

for spatially uniform magnetic induction fields.

Equation 48.10 states that a temporal change in \( \mathbf{B} \) or the mechanical orientation of \( \mathbf{A} \) relative to \( \mathbf{B} \) will produce a terminal voltage. If the coil remains fixed with respect to \( \mathbf{B} \), then static fields cannot be detected; but if the loop is rotated or the magnitude of \( \mathbf{A} \) is changed, then it is possible to measure a static field. The relationship described by Equation 48.10 is exploited in many magnetic field measuring instruments (see [1]).

Figure 48.4 shows the two most common induction coil configurations for measuring field strength: the air core loop antenna and the rod antenna. The operating principle is the same for both configurations. Substituting \( \mu_r \mu_e H(t) \) for \( \mathbf{B} \) in Equation 48.10 and, assuming the loop is stationary with respect to the field vector, the terminal voltage becomes:

\[
e(t) = -\mu_r \mu_e n A \frac{dH(t)}{dt}
\]

where \( n \) is the number of turns in the coil, and \( \mu_e \) is the effective relative permeability of the core. The core of a rod antenna is normally constructed of magnetically “soft” material so one can assume the flux density in the core is induced by an external magnetic field and, therefore, the substitution above is valid. With an air (no) core, the effective relative permeability is one. The effective permeability of an induction

![Figure 48.4](image_url)
coil that contains a core is usually much greater than one and is strongly dependent on the shape of the core and, to some extent, on the configuration of the winding.

Taking the Laplace transform of Equation 48.11 and dividing both sides by $H$, one obtains the following transfer function $T(s)$ for an induction coil antenna:

$$T(s) = -\mu_0\mu_n As = -Ks \left( \text{VmA}^{-1} \right)$$  \hspace{1cm} (48.12)

where $E(s) = T(s) H(s)$, $E(s)$ and $H(s)$ are the Laplace transforms of $e(t)$ and $H(t)$, and $s$ is the Laplace transform operator. Inspection of Equation 48.12 reveals that the magnitude of the coil voltage is proportional to both the magnitude and frequency of the magnetic field being measured. The coil constant or sensitivity of the loop antenna is:

$$K = \mu_0\mu_n A \left( \text{VsmA}^{-1} \right)$$  \hspace{1cm} (48.13)

Figure 48.5 is the equivalent circuit for an induction coil antenna. The actual voltage measured at the terminals of the loop is modified by the inductance $L$, resistance $R$, and the distributed stray and shield capacitances represented by the lumped capacitor $C$. These circuit parameters depend on the geometry of the core, coil, and winding.

The electrostatic shield made of nonmagnetic material shown in Figure 48.4 is an important element in the design of an induction coil. It prevents coupling of electric fields into the coil, thereby assuring that the signal seen at the coil terminals is only that due to a magnetic field. The shield should not be placed too close to the winding since it contributes to coil capacitance and noise.

The Air Core Loop Antenna

The air core loop antenna consists of a circular or rectangular loop containing one or more turns of wire and no magnetic core. The diameter of the loop is usually much greater than the dimensions of the winding cross-section. The sensitivity of a circular loop antenna with a winding inside diameter $d$ and rectangular cross-section is approximately:

$$K = \mu_0 n A \left( \frac{d^2}{4} \right) \left[ 1 + 2 \left( \frac{t}{d} \right) + \frac{3}{4} \left( \frac{t}{d} \right)^2 \right]$$  \hspace{1cm} (48.14)

where $t$ is the thickness of the winding and $n$ is the number of turns.

The resistance of the coil is:

$$R = 4n \frac{d}{d_w} \left( 1 + \frac{t}{d} \right) \rho \Omega$$  \hspace{1cm} (48.15)
where \( d_w \) is the diameter of the bare wire and \( \rho \) is its resistivity in \( \Omega \cdot m \) (1.7 \times 10^{-8} \Omega \cdot m \) for copper).

The inductance of the coil is more difficult to compute since it depends heavily on the geometry of the coil. Those who are interested in computing very accurate inductance values for a wide variety of coil shapes should consult [5]. Equation 48.16 is a general expression that gives a good approximation for the inductance of a circular air core coil.

\[
L = \mu_0 n^2 \pi \left( \frac{d}{2} \right)^2 \frac{k}{w} \, \text{H} \tag{48.16}
\]

where \( w \) is the width of the winding, \( \bar{d} \) is the average diameter, and \( k \) is Nagaoka’s constant:

\[
k = \frac{1}{1 + 0.45 \frac{d}{w} + 0.64 \frac{t}{d} + 0.84 \frac{t}{w}} \tag{48.17}
\]

The distributed capacitance of the coil contributes the most to the overall antenna capacitance. The parasitic capacitances can usually be ignored. Equation 48.18 can be used to estimate the distributed capacitance of a coil.

\[
C_d = \left[ \frac{\varepsilon_w \varepsilon_i}{\varepsilon_w t_w + \varepsilon_i t_i} \right] \frac{0.018544 \bar{d} w (n_l - 1)}{n_l^2} \tag{48.18}
\]

where \( \varepsilon_w \) is the dielectric constant of the wire insulation, \( \varepsilon_i \) is the dielectric constant of the interlayer insulation if any, \( t_w \) is the thickness of the wire insulation, \( t_i \) is the thickness of the interlayer insulation, and \( n_l \) is the number of layers. Adding a second layer to a single-layer coil significantly increases the capacitance but, as the number of layers increases, the capacitance decreases.

The air core loop antenna is particularly useful for measuring magnetic fields with frequencies from 100 Hz to several megahertz. Because it has a linear response to magnetic field strength, it has virtually no intermodulation distortion. On the negative side, the size of the sensor can get quite large for applications that require high sensitivities at low frequencies.

**The Rod Antenna**

The rod antenna is a good alternative to an air core loop antenna. It is smaller in size than a loop antenna with the same sensitivity, and it can be designed to operate at lower frequencies. Unfortunately, its response to magnetic field strength can be nonlinear and the core adds noise.

Figure 48.4(b) is a typical configuration for a rod antenna. It is basically a solenoid with a magnetic core. The core can have a circular or rectangular cross-section and can be made from a ferrite, a nickel-iron alloy, an amorphous metal glass alloy, or some other material with high relative permeability. The winding can be wound directly on the core or on a form through which the core is inserted. Insulation is sometimes placed between layers of the winding to reduce distributed capacitance. An electrostatic shield is placed around the winding to attenuate any electric field coupling into the signal. The shield has a gap that runs the length of the winding. This prevents circulating currents in the shield from attenuating the magnetic field within the coil.

The most common rod antenna configuration is a core with a circular cross-section and a tightly coupled winding that runs most of the length of the core. The sensitivity of the rod antenna is computed by substituting \( \mu_e \) in Equation 48.13 with the following:

\[
\mu_e = 1 + \left( \frac{d}{d + t} \right)^2 \left( \bar{\mu} - 1 \right) \tag{48.19}
\]
where $d_c$ is the core diameter and $\mu$ is the core average effective permeability. The core effective or apparent permeability depends on its geometry and initial permeability, as well as the winding length relative to the core length. A rod becomes magnetized when a magnetic field is applied to it. In response, a magnetic field is created within the rod that opposes the externally applied field and reduces the flux density. The demagnetizing field is proportional to the magnetization and the net field $H$ in the core is:

$$H = H' - NM$$

(48.20)

where $H'$ is the applied external field, $N$ is the demagnetizing factor, and $M$ is the magnetization. The apparent relative permeability of a core is the ratio of the flux density $B$ in the middle of the core to the flux density in air:

$$\frac{B}{\mu_a H'} = \mu_a = \frac{\mu_i}{1 + N(\mu_i - 1)}$$

(48.21)

where $\mu_i$ is the initial relative permeability of the core material. Initial relative permeability is the slope of the $B$–$H$ magnetization curve near zero applied field for a closed magnetic path.

The value of $N$ is shape dependent. As the length-to-diameter ratio $m$ of a rod increases, $N$ decreases and the apparent relative permeability approaches the initial permeability. Table 48.3, which is reproduced from [6], lists demagnetizing factors for a rod, prolate ellipsoid (cigar shape), and oblate ellipsoid (disk shape).

</table>

Equation 48.22 can be used to approximate the value of $N$ for cylindrical rods with $m > 10$ and $\mu_i > 1000$:

$$N = \frac{2.01 \times \log_{10} m - 0.46}{m^2}$$

(48.22)

The apparent permeability of a rod with a small $m$ and large $\mu_i$ is almost exclusively determined by $m$ alone. Table 48.4 lists the magnetic properties of several ferromagnetic materials that can be used to construct a core.

Bozorth [7] found that the apparent permeability of a rod is not constant throughout the length of the rod. It reaches a maximum at the center of the rod and continuously drops in value until the ends of the rod are reached. The variation in permeability can be approximated by:
where \( l \) is the distance from the center of the rod to the measurement point, \( l_0 \) is the half length of the rod, and \( F \) is a constant that varies from 0.72 to 0.96. The average permeability seen by the coil is the integral of Equation 48.23 over the length of the coil:

\[
\bar{\mu} = \mu_s \left[ 1 - F \left( \frac{l}{l_0} \right)^2 \right] (48.24)
\]

where \( l_w \) is the length of the winding and \( l_c \) is the length of the core. Equation 48.24 is substituted into Equation 48.19 to compute the rod’s effective relative permeability which is used in Equation 48.13 to compute sensitivity.

The inductance of the rod antenna can be computed using the following equations:

\[
L = \frac{\mu_s \mu_r \pi (d+t)^2 l_w}{4l_c} (48.25)
\]

\[
\mu_r = 1 + \left( \frac{d}{d+t} \right)^2 \left[ \mu_s f \left( \frac{l_w}{l_c} \right) - 1 \right] (48.26)
\]

\[
f \left( \frac{l_w}{l_c} \right) = 1.9088 - 0.8672 \left( \frac{l_w}{l_c} \right) - 1.1217 \left( \frac{l_w}{l_c} \right)^2 + 0.8263 \left( \frac{l_w}{l_c} \right)^3 (48.27)
\]

The function \( f(l_w/l_c) \) accounts for the variation in flux density from the middle of the winding to its ends and assumes the winding is centered about the middle of the core.

Equations 48.15 and 48.16 can be used to compute the resistance and capacitance of a rod antenna.

**Signal Conditioning**

To be useful, the induction coil signal must be conditioned using either a voltage or a current amplifier. Figure 48.6 illustrates the circuit configurations for both of these signal conditioning methods. The voltage

![Table 48.4 Magnetic Properties of Typical Core Material](image)

Note: \( \mu_s \) is the slope of the magnetization curve at the origin. \( \mu_{max} \) is the maximum incremental slope of the magnetization curve.

\[
\mu(l) = \mu_s \left[ 1 - F \left( \frac{l}{l_0} \right)^2 \right] (48.23)
\]
amplifier can have either a single-ended or differential input and it can be tuned or untuned. The signal output of the voltage amplifier is proportional to the magnitude and frequency of the field for frequencies well below resonance. Its output will peak at the resonant frequency of the coil or at the tuning frequency. Because its output signal depends on both the frequency and strength of the magnetic field, the voltage amplifier is more suited to narrow band or tuned frequency applications.

In the current amplifier configuration, the induction coil terminals are connected to a virtual ground. As long as the product of the amplifier forward gain and the coil ohmic resistance is much greater than the feedback resistor, the output signal magnitude is independent of the frequency of the magnetic field beyond the $\frac{R}{L}$ (rad s$^{-1}$) corner of the coil. This remains true up to the coil’s resonant frequency. For this reason, the current amplifier configuration is particularly suited to broadband magnetic field strength measurements. The current amplifier configuration minimizes intermodulation distortion in induction coils with magnetic cores. The current flowing through the coil produces a magnetic field that opposes the ambient field. This keeps the net field in the core near zero and in a linear region of the $B$–$H$ curve.

Current-amplifier-based induction coil magnetometers have been built that have a flat frequency response from 10 Hz to over 200 kHz. Some magnetometers designed for geophysical exploration applications have low frequency corners that extend down to 0.1 Hz. For further information on this subject, see [8, 9].

The Fluxgate Magnetometer

The fluxgate magnetometer has been and is the workhorse of magnetic field strength instruments both on Earth and in space. It is rugged, reliable, physically small, and requires very little power to operate. These characteristics, along with its ability to measure the vector components of magnetic fields over a
0.1 nT to 1 mT range from dc to several kHz, make it a very versatile instrument. Geologists use them for exploration and geophysicists use them to study the geomagnetic field (about 20 μT to 75 μT on the Earth’s surface). Satellite engineers use them to determine and control the attitude of spacecraft, scientists use them in their research, and the military uses them in many applications, including mine detection, vehicle detection, and target recognition. Some airport security systems use them to detect weapons.

The Fluxgate

The heart of the magnetometer is the fluxgate. It is the transducer that converts a magnetic field into an electric voltage. There are many different fluxgate configurations. Two of the more popular ones are shown in Figure 48.7. A very comprehensive explanation of the fluxgate principle and the different fluxgate configurations is given in [10].

The ring core fluxgate is constructed from a thin ribbon of easily saturable ferromagnetic material, such as 4-79 Permalloy wrapped around a bobbin to form a ring or toroid. As shown in Figure 48.8, an alternating current is applied through a coil that is wound about the toroid. This creates a magnetic field that circulates around the magnetic core. This magnetic field causes the flux in the ferrous material to periodically saturate first clockwise and then counterclockwise. A pick-up (signal) winding is wrapped around the outside of the toroid. While the ferrous material is between saturation extremes, it maintains an average permeability much greater than that of air. When the core is in saturation, the core permeability
becomes equal to that of air. If there is no component of magnetic field along the axis of the signal winding, the flux change seen by the winding is zero. If, on the other hand, a field component is present along the signal winding axis, then each time the ferrous material goes from one saturation extreme to the other, the flux within the core will change from a low level to a high level. According to Faraday’s law, a changing flux will produce a voltage at the terminals of the signal winding that is proportional to the rate of change of flux. For dc and low-frequency magnetic fields, the signal winding voltage is:

\[ e(t) = nA \frac{d[\mu_0 \mu_e H(t)]}{dt} = nA \mu_e H \frac{d\mu_e(t)}{dt} \]  \hspace{1cm} (48.28)

where \( H \) = Component of the magnetic field being measured  
\( n \) = Number of turns on the signal winding  
\( A \) = Cross-sectional area of the signal winding  
\( \mu_e (t) \) = Effective relative permeability of the core

**FIGURE 48.8** The excitation field of a fluxgate magnetometer alternately drives the core into positive or negative saturation, causing the core’s effective permeability to switch between 1 and a large value twice each cycle.
As the core permeability alternates from a low value to a high value, it produces a voltage pulse at the signal winding output that has an amplitude proportional to the magnitude of the external magnetic field and a phase indicating the direction of the field. The frequency of the signal is twice the excitation frequency since the saturation-to-saturation transition occurs twice each excitation period.

The discussion about effective permeability in the induction coil section applies here as well. Consult [10, 13] for comprehensive discussions about fluxgate effective permeability and signal characteristics as they relate to excitation field level, excitation waveform, and winding geometry.

**Signal Conditioning**

The signal from the fluxgate is an amplitude-modulated suppressed carrier signal that is synchronous with the second harmonic of the excitation signal. In a simple low-power magnetometer, this signal is converted to the base band using a synchronous demodulator, filtered, and presented as the final output. Example circuits are given in [11, 12]. The accuracy of magnetometers that use this open-loop architecture is limited by the linearity of the core's magnetization curve and is about 5% for Earth's field (60 μT) applications.

More precise and stable magnetometers use magnetic field feedback rather than the open-loop structure described above. A simplified schematic of a typical second harmonic field feedback fluxgate magnetometer is shown in Figure 48.9. The circuitry to the left of the fluxgate is called the excitation circuit. It consists of an oscillator tuned to twice the excitation frequency, a flip-flop that divides the oscillator frequency by two, and a power amplifier driven by the flip-flop and, in turn, provides the excitation current to the excitation winding.

The circuitry to the right of the fluxgate is called the signal channel circuit. It amplifies the output from the fluxgate signal winding, synchronously demodulates the ac signal using the oscillator signal as a reference, integrates and amplifies the base band output, and then feeds back the output through a resistor to the signal winding. The fed-back signal produces a magnetic field inside the sensor that opposes the external field. This keeps the field inside the sensor near zero and in a linear portion of the magnetization curve of the ferromagnetic core.

The flow diagram for the magnetometer is given in Figure 48.10. The external field \( H_e \) is opposed by the feedback field \( H_f \), and the difference is converted into a voltage signal (\( K_s \) represents the transfer function from field to voltage). This signal is amplified (\( A \)), and the amplified signal is converted into a current \( I_f \) and then into the feedback field (\( K_c \) represents the transfer function from current to field). The overall transfer function for the magnetometer is:

\[
\frac{V_o}{H_e} = \frac{AK_s}{1 + \frac{K_cAK_s}{R_f}}
\]  

(48.29)
The amplifier gain is normally very high such that the second term in the denominator is much larger than one, and Equation 48.29 reduces to

\[
\frac{V_o}{H_a} = \frac{R_f}{K_c}
\]  

(48.30)

Under these circumstances, the transfer function becomes almost completely determined by the ratio of \( R_f \) (the feedback resistor) to \( K_c \) (the current-to-field coil constant of the sensor winding). Both of these constants can be very well controlled. The consequence of this circuit topology is a highly stable and accurate magnetometer that is insensitive to circuit component variations with temperature or time. An accuracy of 1% over a temperature range of \(-80^\circ C\) to \(80^\circ C\) is easily achievable. Accuracy and stability can be improved using a current feedback circuit, like the one described in [13], that compensates for the resistance of the signal winding or by using a separate feedback winding and a high-quality voltage-to-current converter instead of a simple feedback resistor.

The SQUID Magnetometer

Brian D. Josephson in 1962, while a graduate student at Cambridge University, predicted that superconducting current could flow between two superconductors that are separated by a thin insulation layer. The magnitude of the superconductor (critical) current through this "Josephson junction" is affected by the presence of a magnetic field and forms the basis for the SQUID magnetometer.

Figure 48.11 illustrates the general structure of a Josephson junction and the voltage–current (\(V–I\)) relationship. Two superconductors (e.g., niobium) are separated by a very thin insulating layer (e.g., aluminum oxide). The thickness of this layer is typically 1 nm. When the temperature of the junction is reduced to below 4.2 K (\(–269^\circ C\)), a superconductor current will flow in the junction with 0 V across the junction. The magnitude of this current, called the critical current \(I_c\), is a periodic function of the magnetic flux present in the junction. Its maximum magnitude occurs for flux values equal to \(n\phi_0\), where \(\phi_0\) is one flux quantum (2 \(fW\)), and its minimum magnitude occurs for flux values equal to \((n + \frac{1}{2})\phi_0\). The period is one flux quantum. This phenomenon is called the "dc Josephson effect" and is only one of the "Josephson effects."

Magnetometers based on the Superconducting Quantum Interference Device (SQUID) are currently the most sensitive instruments available for measuring magnetic field strength. SQUID magnetometers measure the change in the magnetic field from some arbitrary field level; they do not intrinsically measure the absolute value of the field. Biomedical research is one of the more important applications of SQUID magnetometers. SQUID magnetometers and gradiometers (measure spatial variation in the magnetic field) have the high sensitivities needed to measure the weak magnetic fields generated by the body [15].
Other application areas include paleomagnetics (measuring remnant magnetism in rocks) and magnetotellurics (Earth resistivity measurements). Descriptions of these applications as well as the general theory of SQUIDs can be found in [16]. Clark [17], one of the pioneers in SQUID magnetometers, provides a good contemporary overview of SQUID technology and applications.

A dc SQUID magnetometer uses two Josephson junctions in the two legs of a toroid as shown in Figure 48.12(a). The toroid is biased with a constant current that exceeds the maximum critical current of the junctions. When the flux through the toroid is an integral multiple of $\phi_0$, the voltage across the junctions is determined by the intersection of $I_b$ and the $n \phi_0 V-I$ curve (point A). As the flux increases, the critical current decreases. The $V-I$ curve and thus the intersection point move to the right (the junction voltage increases). The critical current reaches a minimum when the flux has increased by $\frac{1}{2} \phi_0$ and the junction voltage is at its maximum (point B). As the flux continues to increase, the critical current increases back toward its maximum value and the junction voltage decreases. Thus, the period of the flux cycle is $\phi_0$.

**Signal Conditioning**

Figure 48.13 is a block diagram of one implementation of a dc SQUID magnetometer that can be used for wide dynamic range field measurements. A large superconducting loop, which is exposed to the magnetic field being measured, is connected to a multiturn signal winding that is magnetically coupled directly to the SQUID. At cryogenic temperatures, the loop and signal winding effectively form a dc induction coil. External flux applied to the coil will generate a current in the loop that keeps the net flux within the loop constant, even for dc magnetic fields. The signal winding magnifies the flux that is applied to the SQUID.

The SQUID is magnetically biased at an optimal sensitivity point. A small ac magnetic field at 100 kHz to 500 kHz is superimposed on the bias field. The output of the SQUID is a suppressed carrier amplitude modulated signal where the amplitude indicates the change in magnetic field from the bias point, and the phase indicates the polarity of the change. The output signal is amplified and then synchronously demodulated down to the base band. The resulting dc signal is amplified and fed back through a resistor to a coil coupled to the SQUID. This current through the coil generates a magnetic field at the SQUID that opposes the applied field. This keeps the SQUID operating point very near the bias point. The scale

---

**FIGURE 48.11** The Josephson junction in (a) consists of a superconductor such as niobium separated by a thin insulation layer. The voltage ($V$) vs. current ($I$) curve in (b) shows that a superconducting current flows through the junction with zero volts across the junction.
factor of the magnetometer depends on the feedback resistor and the coil constant of the feedback winding in the same manner that it does for a field feedback fluxgate magnetometer.

The pick-up loop, signal coil, SQUID, feedback coil and feedback resistor are kept in a cryogenic temperature chamber and, except for the pick-up coil, are magnetically shielded. The rest of the circuit is operated at room temperature.

48.3 High-Field Vector Gaussmeters

The Hall Effect Gaussmeter

The Hall effect device, which is probably the most familiar and widely used sensor for measuring strong magnetic fields, is based on the discovery of the Hall effect by Edwin H. Hall in 1897. The Hall effect is a consequence of the Lorentz force law, which states that a moving charge \( q \), when acted upon by a magnetic induction field \( \vec{B} \), will experience a force \( \vec{F} \) that is at right angles to the field vector and the velocity vector \( \vec{v} \) of the charge as expressed by the following equation:
The Hall effect device consists of a flat, thin rectangular conductor or semiconductor with two pairs of electrodes at right angles to one another as illustrated in Figure 48.14. An electric field $E_x$ is applied along the $x$ or control axis. When a magnetic field $B_z$ is applied perpendicular to the surface of the device, the free charge, which is flowing along the $x$-axis as a result of $E_x$, will be deflected toward the $y$ or Hall voltage axis. Since current cannot flow in the $y$-axis under open-loop conditions, this will cause a buildup of charge along the $y$-axis that will create an electric field which produces a force opposing the motion of the charge:

$$E_y = v_x B_z$$  \hspace{1cm} (48.32)
where \(v_x\) is the average drift velocity of the electrons (or majority carriers). In a conductor that contains \(n\) free charges per unit volume having an average drift velocity of \(v_x\), the current density is:

\[
J_x = qnv_x
\]  

(48.33)

and

\[
E_y = \frac{J_x B_z}{qn} = R_H J_x B_z
\]  

(48.34)

where \(R_H\) is called the Hall coefficient.

A semiconductor is treated in terms of the mobility \(\mu\) (drift velocity/field) of the majority carrier (electron or hole) and conductivity \(\sigma\). In this case,

\[
E_y = \mu E_x B_z \quad \text{and} \quad E_x = \frac{J_x}{\sigma}
\]  

(48.35)

Therefore,

\[
E_y = \frac{\mu}{\sigma} J_x B_z \quad \text{and} \quad R_H = \frac{\mu}{\sigma}
\]  

(48.36)

The value of \(R_H\) varies substantially from one material to another and is both temperature and field magnitude dependent. Its characteristics can be controlled to a certain extent by doping the base material with some impurities. For example, doping germanium with arsenic can reduce the temperature dependence at the expense of magnitude.

The voltage measured across the \(y\)-axis terminals is the integral of the electric field along the \(y\)-axis. If a constant control current \(I\) is flowing along the \(x\) axis, then:

\[
J_x = \frac{I}{wt}
\]  

(48.37)

and the measured output voltage is:

\[
e_y = \frac{R_H IB_z}{t}
\]  

(48.38)

where \(t\) is thickness (m) and \(w\) is the distance between the \(y\)-axis terminals.

Another characteristic specified by manufacturers of Hall effect devices is the magnetic sensitivity \(\gamma_b\) at the rated control current \(I_c\):

\[
\gamma_b = \frac{e_y}{B_z} = \frac{R_H I_x}{t}
\]  

(48.39)

Although conductors such as copper (Cu) can be used to make a Hall effect device, semiconductor materials, such as gallium arsenide (GaAs), indium antimonide (InSb), and indium arsenide (InAs), produce the highest and most stable Hall coefficients. InAs, because of its combined low temperature coefficient of sensitivity (<0.1%/°C), low resistance, and relatively good sensitivity, is the material favored by commercial manufacturers of Hall effect devices.
The typical control current for Hall effect devices is 100 mA, but some do operate at currents as low as 1 mA. Sensitivities range from 10 mV/T to 1.4 V/T. Linearity ranges from $\frac{1}{4}\%$ to 2% over their rated operating field range. The control input and the voltage output resistance are typically in the range of $1\, \Omega$ to $3\, \Omega$. The sensor element is usually tiny (on the order of 10 mm square by 0.5 mm thick), and a three-axis version can be housed in a very small package. These devices are most effective for measuring flux densities ranging from 50 mT to 30 T.

### Signal Conditioning

A simple Hall effect gaussmeter can be constructed using the signal conditioning circuit shown in Figure 48.15. The voltage reference, operational amplifier, and sense resistor $R_s$ form a precision constant-current source for the Hall effect device control current $I_c$. For best performance, the voltage reference and $R_s$ should be very stable with temperature and time. A general-purpose operational amplifier can be used for low control currents. A power amplifier is required for control currents above 20 mA.

The Hall voltage can be conditioned and amplified by any high input impedance (>1 k$\Omega$) differential amplifier. A precision instrumentation amplifier is a good choice because it has adequate input impedance, its gain can be determined by a stable resistor, and the amplifier zero offset trim resistor can be used to cancel the zero offset of the Hall effect device. Some devices require a load resistor across the Hall voltage terminal to achieve optimum linearity.

The zero offset and 1/f noise of the Hall voltage amplifier limit the performance of a Hall effect gaussmeter for low field strength measurements. Sometimes, these effects can be reduced by using an ac precision current source. The ac amplitude modulated Hall voltage can then be amplified in a more favorable frequency band and synchronously detected to extract the Hall voltage signal. If the field to be measured requires this amount of signal conditioning, it probably is better to use a fluxgate magnetometer for the application.

### The Magnetoresistive Gaussmeter

The magnetoresistance effect was first reported by William Thomson (Lord Kelvin) in the middle of the 19th century. He found that a magnetic field applied to a ferromagnetic material caused its resistivity to change. The amount of change depends on the magnetization magnitude and the direction in which the current used to measure resistivity is flowing. Nickel–iron alloys show the greatest change in resistivity (about 5% maximum). Figure 48.16 illustrates how the resistivity changes in Permalloy (a nickel–iron alloy) for a field applied parallel to the current flow. As magnetic field is increased, the change in resistivity increases and asymptotically approaches its maximum value when the material approaches saturation. Bozorth [6] points out that the shape of the curve and the magnitude of the change depend on the
composition of the alloy. Permalloy with 80% Ni and 20% Fe provides a high magneto resistance effect with near-zero magnetostriction and is a favorite material for magnetoresistors.

The change in resistivity in permalloy film \[18\] is also a function of the angle \( \theta \) between the magnetization direction and the current direction:

\[
\rho(\theta) = \rho_0 + \Delta \rho_m \cos^2 \theta
\]  

(48.40)

where \( \Delta \rho_m \) is the magnetoresistivity anisotropy change and \( \rho_0 \) is the resistivity for \( \theta = \pi/2 \).

It was mentioned earlier that magnetic materials have anisotropic magnetic properties (their magnetic properties are direction dependent). The physical shape of an object (see the discussion on demagnetizing factor above) and the conditions that exist during fabrication strongly determine its anisotropic characteristics. A thin long film of permalloy can be made to have highly uniaxial anisotropic properties if it is exposed to a magnetizing field during deposition. This characteristic is exploited in the anisotropic magnetoresistance (AMR) sensor.

The basic resistor element in an AMR is a thin rectangular shaped film as shown in Figure 48.17. One axis, called the anisotropy or easy axis, has a much higher susceptibility to magnetization than the other two. The easy axis is normally along the length of the film. Because of its thinness, the axis normal to the film has virtually no magnetic susceptibility. The axis transverse to the easy axis (across the width) has very little susceptibility as well.

A bias field \( H_b \) is used to saturate the magnetization along the easy axis and establish the magnetization direction for zero external field. For a simplified analysis, the film can be modeled as a single domain.
The effect of an external field in the plane of the film and normal to the anisotropy axis is to rotate the magnetization vector and, according to Equation 48.40, change the resistivity. Kwiatkowski and Tumanski [19] stated that the change in resistance of the film can be approximated by Equation 48.41:

\[ \Delta R = R_s \frac{\Delta \rho_m}{\rho} \left( h_a^2 \cos 2\theta + h_a \sqrt{1 - h_a^2 \sin 2\theta - \frac{1}{2} \cos 2\theta} \right) \]  

where \( h_a \) is the normalized externally applied field (i.e., \( h_a = H_a/H_k \)), \( R_s \) is the nominal resistance, and \( \Delta \rho_m/\rho \) is the maximum resistivity change. \( H_k \) is the anisotropy field. Optimum linear performance is obtained when \( \theta = \pi/4 \) and Equation 48.41 reduces to:

\[ \Delta R = R_s \frac{\Delta \rho_m}{\rho} \frac{1}{H_a + H_b} H_a \]  

The anisotropy field is given by:

\[ H_k = \sqrt{H_{k0}^2 + (NM_s)^2} \]  

where \( H_{k0} \) is the film anisotropy field, \( N \) is the demagnetizing factor (= thickness(t)/width(w)) and \( M_s \) is the saturation magnetization.

An AMR is constructed using long thin film segments of deposited permalloy. During deposition, a magnetic field is applied along the length of the film to establish its easy axis of magnetization. The shape of the film also favors the length as an easy axis. As shown in Figure 48.18, a series of these permalloy films is connected together to form the magnetoresistor. The current is forced to flow at a 45° angle to the easy axis by depositing thin strips of highly conductive material (e.g., gold) across the permalloy film. The level of magnetization of the film is controlled by a bias field that is created through the deposition of a thin layer of cobalt over the resistors, which is then magnetized parallel to the easy axis of the permalloy.
A typical AMR sensor suitable for a gaussmeter or magnetometer consists of four AMRs connected in a Wheatstone bridge as shown in Figure 48.19. The transfer function polarity of the A and D resistors is made to be opposite that of the B and C resistors by rotating the current shunt 90°. This complimentary arrangement enhances the output voltage signal for a given field by a factor of four over a single resistor. Kwiatkowski and Tumanski [19] showed that the transfer function for the bridge configuration is described by:

\[
\nu = IR \frac{\Delta \rho m \cos 2 \Delta \theta}{p} \sqrt{1 - h^2}
\]

(48.44)

Where:

\[
\cos 2 \Delta \theta = \frac{H_{k0}^2 + H_k^2 - (NM)^2}{2H_{k0}H_k}
\]

(48.45)

\[
h_a = \frac{H_a}{H_k + H_b}
\]

(48.46)

For best linearity, \(H_a < 0.1 \ H_k\). The linearity of the bridge can be controlled during fabrication by adjusting the \(l/w\) ratio and \(H_{k0}\). The bias field can also be used to optimize linearity and establish the measurement field range. Some transfer functions for a typical AMR bridge [20] are shown in Figure 48.20. A more comprehensive discussion of AMR theory can be found in [21–23].

**Signal Conditioning**

Conventional Wheatstone bridge signal conditioning circuits can be used to process the AMR bridge. The bridge sensitivity and zero offset are proportional to the bridge voltage, so it is important to use a well-regulated supply with low noise and good temperature stability.
As Equation 48.44 shows, the polarity of the transfer function is determined by the polarity of \((H_k + H_b)\). If the sensor is exposed to an external field that is strong enough to reverse this field, then the transfer function polarity will reverse. To overcome this ambiguity, the polarity should be established prior to making a measurement. This can be accomplished by momentarily applying a strong magnetic field along the easy axis of the AMR bridge. Some commercial AMR bridges come with a built-in method for performing this action.

Figure 48.21 is a block diagram for a signal conditioner that takes advantage of the bias field polarity flipping property to eliminate zero offset errors and low frequency \(1/f\) noise. A square wave oscillator is used to alternately change the direction of the bias field and thus the polarity of the transfer function. The duration of the current used to set the bias field direction should be short in order to minimize power consumption. The amplitude of the ac signal from the bridge is proportional to the field magnitude, and its phase relative to the oscillator gives the field direction. This signal can be amplified and then phase-detected to extract the field-related voltage. Optionally, the output signal can be fed back through a coil that produces a magnetic field opposing the field being measured. This feedback arrangement makes the AMR bridge a null detector and minimizes the influence of changes in its transfer function on overall performance. Of course, the added circuitry increases the size, cost, and complexity of the instrument.

### 48.4 Scalar Magnetometers

Scalar magnetometers measure the magnitude of the magnetic field vector by exploiting the atomic and nuclear properties of matter. The two most widely used scalar magnetometers are the proton precession and the optically pumped magnetometer. When operated under the right conditions, these instruments have extremely high resolution and accuracy and are relatively insensitive to orientation. They both have several common operating limitations. The instruments require the magnetic field to be uniform throughout the sensing element volume. They have a limited magnetic field magnitude measurement range: typically 20 µT to 100 µT. And they have limitations with respect to the orientation of the magnetic field vector relative to the sensor element.
The proton precession magnetometer uses a strong magnetic field to polarize the protons in a hydrocarbon and then detects the precession frequency of the protons while they decay to the nonpolarized state after the polarizing field is turned off. The precession frequency is proportional to the magnitude of any ambient magnetic field that is present after the polarizing field is removed. This sampling of the magnetic field strength through the polarize-listen sequence makes the proton precession magnetometer response very slow. Maximum rates of only a few samples per second are typical. Because of its dependence on atomic constants, the proton precession magnetometer is the primary standard for calibrating systems used to generate magnetic fields and calibrate magnetometers.

The optically pumped magnetometer is based on the Zeeman effect. Zeeman discovered that applying a field to atoms, which are emitting or absorbing light, will cause the spectral lines of the atoms to split into a set of new spectral lines that are much closer together than the normal lines. The energy-related frequency interval between these hyperfine lines is proportional to the magnitude of the applied field. These energy levels represent the only possible energy states that an atom can possess. The optically pumped magnetometer exploits this characteristic by optically stimulating atoms to produce an overpopulated energy state in one of the hyperfine spectral lines and then causing the energy state to depopulate using an RF magnetic field. The RF frequency required to depopulate the energy state is equal to the spectral difference of the hyperfine lines produced by a magnetic field and, therefore, is proportional to the magnetic field strength. The optically pumped magnetometer can be used to sample the magnetic

---

**FIGURE 48.21** Example AMR gaussmeter. The magnetization direction can be alternately flipped to eliminate zero offset. The resulting ac signal can then be amplified and synchronously phase-detected to recover the field-related signal. Optionally, the range and stability of the AMR gaussmeter can be increased by connecting the output voltage through a resistor to a feedback coil that produces a field that nulls the applied field.
field at a much higher rate than the proton precession magnetometer and generally can achieve a higher resolution. The sample rate and instrument resolution are interdependent.

The Proton Precession Magnetometer

The proton precession magnetometer works on the principle that a spinning nucleus, which has both angular momentum $\mathbf{L}$ and a magnetic moment $\mathbf{\mu}$, will precess about a magnetic field like a gyroscope, as shown in Figure 48.22. The precession frequency $\omega_p$ is proportional to the applied field. When the magnetic field $H_a$ is applied to the nucleus, it will produce a torque:

$$\vec{T} = \mathbf{\mu}_p \times \vec{H}_a$$  \hspace{1cm} (48.47)

on the nucleus. Because the nucleus has angular momentum, this torque will cause the nucleus to precess about the direction of the field. At equilibrium, the relationship between the torque, precession rate, and angular momentum is:

$$\mathbf{\mu}_p \times \vec{H}_a = \vec{\omega}_p \times \vec{L}$$  \hspace{1cm} (48.48)

Solving for the magnitude of the (Larmor) precession frequency, one finds that:

$$\omega_p = \left( \frac{\mathbf{\mu}_p}{L} \right) H_a = \gamma H_a$$  \hspace{1cm} (48.49)

where $\gamma$ is called the gyromagnetic ratio and equals $(2.6751526 \pm 0.0000008) \times 10^{-8}$ T$^{-1}$ s$^{-1}$.

Figure 48.23 is a block diagram of a proton precession magnetometer. The sensor is a container of hydrocarbon rich in free hydrogen nuclei. A solenoid wrapped around the container is used to both polarize the nuclei and detect the precession caused by the ambient field. Before the polarizing field is applied, the magnetic moments of the nuclei are randomly oriented, and the net magnetization is zero. Application of the polarizing field (typically 3 mT to 10 mT) causes the nuclei to precess about the field. The precession axis can be parallel or antiparallel (nuclear magnetic moment pointing in the direction of the field) to the applied field. From a quantum mechanical standpoint, the antiparallel state is a lower energy level than the parallel state. In the absence of thermal agitation, which causes collisions between atoms, the fluid would remain unmagnetized. When a collision occurs, the parallel precession-axis nuclei lose energy and switch to the antiparallel state. After a short time, there are more nuclei with magnetic
moments pointing in the direction of the field than away from it, and the fluid reaches an equilibrium magnetization $\mathcal{M}_0$. The equation that relates magnetization buildup to time is:

$$M(t) = \mathcal{M}_0 \left(1 - e^{-t/\tau_c}\right)$$

(48.50)

where $\tau_c$ is the spin-lattice relaxation time.

The equilibrium magnetization is based on thermodynamic considerations. From Boltzmann statistics for a system with spins of $\frac{1}{2}$:

$$\frac{n_p}{n_a} = e^{2\mu_p H_a/\kappa T}$$

(48.51)

where $n_p$ is the number of precession spin axes parallel to $H_a$, $n_a$ is the number of precession spin axes antiparallel to $H_a$, $\kappa$ is Boltzmann's constant, and $T$ is temperature (kelvin). If $n$ is the number of magnetic moments per unit volume, then:

$$n = n_p + n_a = n_a \left(1 + e^{2\mu_p H_a/\kappa T}\right)$$

(48.52)
and

\[ M_0 = \left( n_p - n_s \right) \mu_p = \frac{n \mu_e^2 H_s}{kT} \]  

(48.53)

Once the fluid has reached equilibrium magnetization, the field is removed and the nuclei are allowed to precess about the local ambient field until they become randomized again. This process of excitation–relaxation can take as long as several seconds.

The hydrocarbon spin-lattice relaxation time can be adjusted by mixing paramagnetic salts, such as ferrous nitrate, into the solution. The trade-off in reduced relaxation time is increased signal-to-noise and resolution. Benzene is a good general-purpose hydrocarbon that can be used in a proton precession magnetometer.

**Signal Conditioning**

The block diagram shown in Figure 48.23 is an example of the signal conditioning required for a proton precession magnetometer. The coil surrounding the bottle containing the hydrocarbon serves two purposes. At the beginning of a measurement, the current source is connected to the coil to generate the magnetic field that polarizes the fluid. This field is on the order of 10 mT. After a few seconds, the current source is disconnected and the coil, which now has a decaying nuclear precession signal at its output, is connected to the input of the amplifier. The signal is amplified, filtered, and then the period of the Larmor frequency is measured, averaged, scaled, and presented to the user in magnetic field units on a digital display.

The scale factor of the proton precession magnetometer is based on the gyromagnetic ratio, which is 0.042579 Hz nT\(^{-1}\). High resolution, up to 0.01 nT, is achieved by measuring the period of the signal rather than the frequency. The signal frequency can be divided down and used to gate a high-frequency oscillator that is driving a counter.

The sampling of the field is controlled manually in many commercially available proton precession magnetometers. Some magnetometers have an internally controlled sample rate. The sample rate and resolution are inversely related to one another. A higher sample rate produces a poorer resolution.

**The Optically Pumped Magnetometer**

As explained earlier, the optically pumped magnetometer is based on the Zeeman effect. This effect is most pronounced in alkaline vapors (rubidium, lithium, cesium, sodium, and potassium). Figure 48.24 is the hyperfine spectral structure for the valence electrons of rubidium (Rb) 85, which is commonly used in these types of magnetometers. The energy-related frequency interval between these hyperfine lines is proportional to the applied field. The magnetic quantum number \( m \) is related to the angular momentum number and specifies the possible component magnitude of the magnetic moment along the applied field. The optically pumped magnetometer takes advantage of this characteristic.

Transitions occur between levels of different \( m \) values and obey the rule that the change in \( m \) can only have the values 0, 1, and –1. Table 48.5 lists the relationship between the polarization of the light stimulating the transition and the allowable change in \( m \).

When not optically excited, the energy states of the valence electrons will be distributed according to Boltzmann statistics and will be in a state of equilibrium. If the electrons are excited with circularly polarized light at the D1 frequency (794.8 nm wavelength), they will absorb photons and transition from the \( ^2S_{1/2} \) state to the \( ^2P_{1/2} \) state according to the transition rules. The excited electrons will then fall back in a random fashion to the lower states, being distributed with an equal probability among all the \( m \) states.

But the rules state that the change in \( m \) can only be 1 or –1 for polarized light. If one uses right circularly polarized light, then the change in \( m \) can only be 1, and the electrons in the \( m = 3 \) level of the \( ^2S_{1/2} \) state cannot transition since there is no \( m = 4 \) level at the \( ^2P_{1/2} \) state. Therefore, these electrons remain in the \( m = 3 \) state. All other electrons transition to the higher state and then fall back to the lower state.
with equal probability of arriving at any of the \( m \) levels, including \( m = 3 \). Thus, the \( m = 3 \) level fills up, and the other levels empty until all the electrons are in the \( m = 3 \) level, and no more transitions to the higher state can take place. Pumping stops.

When pumping begins, the vapor is opaque. As time goes on, less electrons are available for absorbing photons, and the vapor becomes more transparent until, finally, pumping action stops and the vapor is completely transparent.

If a small RF magnetic field at the Larmor frequency is applied at right angles to the magnetic field being measured, the electrons in the \( m = 3 \) state will be depumped to the other \( m \) levels, making them available for further pumping. The optically pumped magnetometer exploits this situation in a positive feedback arrangement to produce an oscillator at the Larmor frequency.

The scale factors for optically pumped magnetometers are significantly higher than for the proton precession magnetometer. Table 48.6 lists these scale factors for a number of alkali vapors.
As a result, the sample rate and resolution can be much higher. A resolution of 0.005 nT is possible.

Sampling rates can be as high as 15 samples per second.

**Signal Conditioning**

Descriptions of several optically pumped magnetometers and their operating principles can be found in [24–26]. There are a number of different signal conditioning arrangements that can be used to derive a useful readout of the measured fields. Two of the more common methods are described in [26] and are shown in Figure 48.25.

In the servoed type shown in Figure 48.25(a), the magnetic field being measured and the RF field are coaxial. The frequency of the RF oscillator is modulated with a fixed low-frequency oscillator. This causes the RF frequency to sweep through the Larmor frequency. If the swept RF oscillator is not centered about the Larmor frequency, the photocell output signal will contain a fundamental component of the RF modulation frequency. The phase of the signal relative to the modulator oscillator determines whether the central RF frequency is above or below the Larmor frequency. The photocell output is phase-detected to produce an error voltage that is used to drive the RF frequency toward the Larmor frequency. The RF frequency can be measured to determine the magnetic field. If a linear voltage controlled oscillator is used as the RF oscillator, its control voltage can also be used as an output since it is a measure of the Larmor frequency.

The auto-oscillating type shown in Figure 48.25(b) is based on the transmission of a polarized beam that is at right angles to the field being measured. The intensity of this cross-beam will be modulated at the Larmor frequency. The photocell signal will be shifted by 90° relative to the RF field. By amplifying the photocell signal, shifting it 90° and feeding it back to drive the RF field coil, an oscillator is created at the Larmor frequency. In practice, only one light source is used, and the field being measured is set at an angle of 45°.

**Defining Terms**

**Anisotropic:** The material property depends on direction.

**Gaussmeter:** An instrument used to measure magnetic fields greater than 1 mT.

**Induced magnetization:** The object’s magnetization is induced by an external magnetic field and disappears when the inducing field is removed.

**Initial permeability:** The slope at the origin of the magnetization curve.

**Isotropic:** The material property is the same in all directions.

**Magnetic dipole moment:** A vector quantity that describes the strength and direction of a magnetic field source, such as a small current loop or spinning atomic nucleus.

**Magnetically “hard” material:** The material has a significant residual (permanent) magnetization after an external magnetic field is removed.

**Magnetically “soft” material:** The material’s magnetization is induced by an external magnetic field and the material has no significant residual (permanent) magnetization after the field is removed.

Magnetization curve: A plot of flux density $B$ vs. magnetic field $H$ for an initially unmagnetized ferromagnetic material.

Magnetization: A vector quantity describing the average density and direction of magnetic dipole moments.

FIGURE 48.25 Two examples of optically pumped scalar magnetometers. The servoed magnetometer: (a) slightly modulates the RF field at a low frequency, causing the vapor transmissivity to modulate. A phase detector provides an error signal that is used to lock the RF oscillator to the Larmor frequency. (b) A self-oscillating magnetometer: the transmissivity of the vapor, at right angles to the applied field, is made to oscillate at the Larmor frequency by phase-shifting the detected light modulation and feeding it back to the RF field generator. (Adapted from Hartmann, 1972.)
**Magnetometer:** An instrument used to measure magnetic fields with magnitudes up to 1 mT.

**Magnetoresistance:** The change in the electrical resistivity of a material in response to an applied magnetic field.

**Maximum permeability:** The maximum slope of the line drawn from the origin of the magnetization curve to a point on the magnetization curve.

**Permanent magnetization:** The source of an object’s magnetization is internal and does not depend on the presence of an external field.

**Permeability:** A function that describes the relationship between an applied magnetic field and the resulting flux density.

**Relative permeability:** The permeability of a material normalized (divided) by the permeability of a vacuum.

**Scalar magnetometer:** A magnetometer that measures the magnitude of a magnetic field vector.

**Vector magnetometer:** A magnetometer that measures one or more of the individual components of a magnetic field vector.

49.6 Validity of Measurements

Magnetic fields are typically conceptualized with so-called “flux lines” or “lines of force.” When such flux lines encounter any sort of matter, an interaction takes place in which the number of flux lines is either increased or decreased. The original magnetic field therefore becomes amplified or diminished in the body of matter as a result of the interaction. This is true whether the matter is a typical “magnetic” material, such as iron or nickel, or a so-called “nonmagnetic” material, such as copper or air.

The magnetic permeability of a substance is a numerical description of the extent to which that substance interacts with an applied magnetic field. In other words, permeability refers to the degree to which a substance can be magnetized.

Different substances possess varying degrees of magnetization. The aforementioned examples of strongly magnetic materials have the ability to strengthen an applied magnetic field by a factor of several thousand. Such highly magnetizable materials are called ferromagnetic. Certain other substances, such as Al, only marginally increase an applied magnetic field. Such weakly magnetizable materials are called paramagnetic. Still other substances, such as Cu and the rare gases, slightly weaken an applied magnetic field. Such “negatively magnetizable” substances are called diamagnetic.

In common parlance, diamagnetic and paramagnetic substances are often called nonmagnetic. However, as detailed below, all substances are magnetic to some extent. Only empty space is truly nonmagnetic.

The term hysteresis has been used to describe many instances where an effect lags behind the cause. However, Ewing was apparently the first to use the term in science [1] when he applied it to the particular magnetic phenomenon displayed by ferromagnetic materials. Magnetic hysteresis occurs during the cyclical magnetization of a ferromagnet. The magnetization path created while increasing an externally applied field is not retraced on subsequent decrease (and even reversal) of the field. Some magnetization, known as remanence, remains in the ferromagnet after the external field has been removed. This remanence, if appreciable, allows for the permanent magnetization observed in common bar magnets.
49.1 Definition of Permeability

Let an externally applied field be described by the vector quantity $\mathbf{H}$. This field may be produced by a solenoid or an electromagnet. Regardless of its source, $\mathbf{H}$ has units of amperes turns per meter ($\text{A m}^{-1}$). On passing through a body of interest, $\mathbf{H}$ magnetizes the body to a degree, $\mathbf{M}$, formally defined as the magnetic moment per unit volume. The units of $\mathbf{M}$ are usually webers per square meter. A secondary coil (and associated electronics) is typically used to measure the combined effects of the applied field and the body’s magnetization. This sum total flux-per-unit-area (flux density) is known as the induction, $\mathbf{B}$, which typically has units of Wb/m$^2$, commonly referred to as a Tesla (T). Because $\mathbf{H}$, $\mathbf{M}$, and $\mathbf{B}$ are usually parallel to one another, the vector notation can be dropped, so that:

$$B = \mu_0 H + M$$

(49.1)

where $\mu_0$ is the permeability of free space ($4\pi \times 10^{-7} \text{ Wb/Am}$).

The absolute permeability, $\mu$, of a magnetized body is defined as the induction achieved for a given strength of applied field, or:

$$\mu = \frac{B}{H}$$

(49.2)

Often, the absolute permeability is normalized by $\mu_0$ to result in the relative permeability, $\mu_r (= \mu/\mu_0)$. This relative permeability is numerically equal and physically equivalent to the cgs version of permeability. This, unfortunately, is still in common usage, and often expressed in units of gauss per oersted (G Oe$^{-1}$), although the cgs permeability is actually dimensionless. Conversion factors between the mks and cgs systems are listed in Table 49.1 for the important quantities encountered.

49.2 Types of Material Magnetization

All substances fall into one of three magnetic groups: diamagnetic, paramagnetic, or ferromagnetic. Two important subclasses, antiferromagnetic and ferrimagnetic, will not be included here. The interested reader can find numerous discussions of these subclasses; for example, see [1].

Diamagnetism

Diamagnetic and paramagnetic (see next section) substances are usually characterized by their magnetic susceptibility rather than permeability. Susceptibility is derived by combining Equations 49.1 and 49.2, viz.

$$\mu_r = 1 + \frac{M}{\mu_0 H} = 1 + \frac{\kappa}{\mu_0}$$

(49.3)

where $k$ is the susceptibility with units of Wb A$^{-1}$ m$^{-1}$. This so-called volume susceptibility is often converted to a mass susceptibility ($\chi$) or a molar susceptibility ($\chi_M$). Values for the latter are readily available for many pure substances and compounds [2]. Susceptibility is also often called “intrinsic permeability” [3].

In any atom, the orbiting and spinning electrons behave like tiny current loops. As with any charge in motion, a magnetic moment is associated with each electron. The strength of the moment is typically expressed in units of Bohr magnetons.

Diamagnetism represents the special case in which the moments contributed by all electrons cancel. The atom as a whole possesses a net zero magnetic moment. An applied field, however, can induce a moment in the diamagnetic material, and the induced moment opposes the applied field. The magnetization, $M$, in Equation 49.3 is therefore antiparallel to the applied field, $H$, and the susceptibility, $k$, is negative. For diamagnetic materials, $\mu < 1$. Figure 49.1 shows a schematic $M$ vs. $H$ curve for graphite with $k = -1.78 \times 10^{-11}$ Wb A$^{-1}$ m$^{-1}$. Note that $k$ is a constant up to very high applied field values.

**Paramagnetism**

In a paramagnetic substance, the individual electronic moments do not cancel and the atom possesses a net nonzero moment. In an applied field, the weak diamagnetic response is dominated by the atom’s tendency to align its moment parallel with the applied field’s direction. Paramagnetic materials have relatively small positive values for $k$, and $\mu > 1$.

Thermal energy retards a paramagnet’s ability to align with an applied field. Over a considerable range of applied field and temperature, the paramagnetic susceptibility is constant. However, with very high applied fields and low temperatures, a paramagnetic material can be made to approach saturation — the condition of complete alignment with the field. This is illustrated in Figure 49.2 for potassium chromium alum, a paramagnetic salt. Even at a temperature as low as 1.30 K, an applied field in excess of about $3.8 \times 10^6$ A m$^{-1}$ is necessary to approach saturation. [Note in Figure 49.2, that 1 Bohr magneton = $9.27 \times 10^{-24}$ J T$^{-1}$.]

---

**FIGURE 49.1** For diamagnetic substances, magnetization $M$ is small and opposite the applied field $H$ as in this schematic example for graphite ($k = -1.78 \times 10^{-11}$ Wb A$^{-1}$ m$^{-1}$).
Ferromagnetism

Ferromagnetic substances are actually a subclass of paramagnetic substances. In both cases, the individual electronic moments do not cancel, and the atom has a net nonzero magnetic moment that tends to align itself parallel to an applied field. However, a ferromagnet is much less affected by the randomizing action of thermal energy compared to a paramagnet. This is because the individual atomic moments of a ferromagnet are coupled in rigid parallelism, even in the absence of an applied field.

With no applied field, a demagnetized ferromagnet is comprised of several magnetic domains. Within each domain, the individual atomic moments are parallel to one another, or coupled, and the domain has a net nonzero magnetization. However, the direction of this magnetization is generally opposed by a neighboring domain. The vector sum of all magnetizations among the domains is zero. This condition is called the state of spontaneous magnetization.

With an increasing applied field, domains with favorable magnetization directions, relative to the applied field direction, grow at the expense of the less favorably oriented domains. This process is schematically illustrated in Figure 49.3. The exchange forces responsible for the ferromagnetic coupling are explained by Heisenberg’s quantum mechanical model [4]. Above a critical temperature known as the Curie point, the exchange forces disappear and the formerly ferromagnetic material behaves exactly like a paramagnet.

During magnetization, ferromagnets show very different characteristics from diamagnets and paramagnets. Figure 49.4 is a so-called $B$–$H$ curve for a typical soft ferromagnet. Note that $B$ is no longer
FIGURE 49.3 With no applied field (a) a ferromagnet assumes spontaneous magnetization. With an applied field (b) domains favorably oriented with $H$ grow at the expense of other domains.

FIGURE 49.4 Magnetization ($B$-$H$) curve for a typical soft ferromagnet. Permeability at point $(H', B')$ is the slope of the dashed line.
linear with $H$ except in the very low- and very high-field regions. Because of this, the permeability $\mu$ for a ferromagnet must always be specified at a certain applied field, $H$, or, more commonly, a certain achieved induction, $B$. Note that $\mu$ is the slope of the line connecting a point of interest on the $B$–$H$ curve to the origin. It is not the slope of the curve itself, although this value, $dB/dH$, is called the differential permeability [3].

Another ferromagnetic characteristic evident in Figure 49.4 is saturation. Once the applied field has exceeded a certain (and relatively low) value, the slope of the magnetization curve assumes a constant value of unity. At this point, $M$ in Equation 49.1 has reached a maximum value, and the ferromagnet is said to be saturated. For all practical purposes, all magnetic moments in the ferromagnet are aligned with the applied field at saturation. This maximum magnetization is often called the saturation induction, $B_s$ [5]. Note that $B_s$ is an intrinsic property — it does not include the applied field in its value.

49.3 Definition of Hysteresis

If $H$ is decreased from $H_M$ in Figure 49.4, $B$ does not follow the original magnetization path in reverse. Even if $H$ is repeatedly cycled from $H_M$ to $-H_M$, $B$ will follow a path on increasing $H$ that is different from decreasing $H$. The cyclical $B$–$H$ relationship for a typical soft ferromagnet is displayed by the hysteresis loops in Figure 49.5. Two loops are included: a minor loop inside a major loop generated by independent measurements. The two differ in the value of maximum applied field: $H_M'$ for the minor loop was below saturation while $H_M^*$ for the major loop was near saturation. Both loops are symmetrical about the origin as a point of inversion since in each case $H = -H_M$.

Notice for the minor loop that when the applied field is reduced from $H_M'$ to 0, the induction does not also decrease to zero. Instead, the induction assumes the value $B_r$, known as the residual induction. If the peak applied field exceeds the point of saturation, as for the major loop in Figure 49.5, $B_r$ assumes a maximum value known as the retentivity, $B_{r}$.

Note that $B_r$ and $B_{r}$ are short-lived quantities observable only during cyclical magnetization conditions. When the applied field is removed, $B_r$ rapidly decays to a value $B_{r}$ known as the remanent induction. $B_{r}$ is a measure of the permanent magnetization of the ferromagnet. If the maximum applied field was in excess of saturation, $B_{r}$ rapidly decays to a maximum value of permanent magnetization, or remanence, $B_{dm}$.

The minor loop in Figure 49.5 shows that in order to reduce the induction $B$ to zero, a reverse applied field, $H_c$, is needed. This is known as the coercive force. If the maximum applied field was in excess of saturation, the coercive force assumes a maximum value, $H_{c}$, known as the coercivity. Note that $H_{c}$ and $H_{c}$ are usually expressed as positive quantities, although they are negative fields relative to $H_M'$ and $H_M^*$.

The hysteresis loops in Figure 49.5 are known as $dc$ loops. Typical sweep times for such loops range from 10 s to 120 s. At faster sweep times, the coercivity will show a frequency dependence, as shown experimentally in Figure 49.6. For soft magnetic materials, this dependence can be influenced by the metallurgical condition of the ferromagnet [6].

49.4 Core Loss

During ac magnetization, some of the input energy is converted to heat in ferromagnetic materials. This heat energy is called core loss and is classically comprised of three parts. The first, hysteresis loss, $P_h$, is proportional to the ac frequency, $f$, and the area of the (slow-sweep) dc hysteresis loop:

$$P_h = kf\int BdH$$  \hspace{1cm} (49.4)

The second part is the loss due to eddy current formation, $P_e$. In magnetic testing of flat-rolled strips (e.g., the Epstein test; see next section), this core loss component is classically expressed as
The sum total $P_h + P_c$ almost never equals the observed total core loss, $P_t$. The discrepancy chiefly originates from the assumptions made in the derivation of Equation 49.5. To account for the additional observed loss, an anomalous loss term, $P_a$, has often been included, so that

$$P_t = P_h + P_c + P_a$$

where $B = $ Peak induction

$t = $ Strip thickness

$d = $ Material density

$\rho = $ Material resistivity

FIGURE 49.5 Major and minor dc hysteresis loops for a typical soft ferromagnet. Labeled points of interest are described in the text.
Reference [3] is a good source for the various accepted test methods for permeability and hysteresis in diamagnetic, paramagnetic, and ferromagnetic materials. Unfortunately, only a few of the instruments described there are available commercially. Examples of these are listed in Table 49.2.

### 49.5 Measurement Methods

With increasing test frequency, coercivity for a soft ferromagnet also increases.

* D — diamagnetic, P — paramagnetic, F — ferromagnetic.
The instruments in Table 49.2 include hysteresigraphs (LDJ models 3500, 5600, and 5500) and vibrating sample magnetometers (LDJ and Lakeshore Cryotronics VSM models). Also included are two Donart models of Epstein testers. The Epstein test is commonly used to characterize flat-rolled soft ferromagnets such as silicon electrical steels in sheet form. A recent alternative to the Epstein test is the single-sheet test method. The Soken instrument in Table 49.2 is an example of such a tester. This method requires much less sample volume than the Epstein test. It can also accommodate irregular sample geometries. However, the Soken instrument is not yet accepted by the American Society for Testing and Materials (ASTM) for reasons explained in the next section.

Note that all instruments in Table 49.2 can measure permeability (or susceptibility), but not all can provide hysteresis loop measurements. Diamagnetic and paramagnetic materials generally require VSM instruments unless one is prepared to construct their own specialty apparatus [3]. All instruments in Table 49.2 can measure ferromagnetic materials, although only a few can accommodate hard (i.e., permanently magnetizable) ferromagnets.

The price ranges in Table 49.2 account for such options as temperature controls, specialized test software, high-frequency capabilities, etc.

49.6 Validity of Measurements

For a ferromagnet under sinusoidal ac magnetization, the induction will show a waveform distortion (i.e., $B$ is nonsinusoidal) once $H_m$ exceeds the knee of the $B$–$H$ curve in Figure 49.4. Brailsford [7] has discussed such waveform distortion in detail. With one exception, all ac instruments in Table 49.2 determine $H$ from its sinusoidal waveform and $B$ from its distorted waveform.

The single exception is the Soken instrument. Here, feedback amplification is employed to deliberately distort the $H$ waveform in a way necessary to force a sinusoidal $B$ waveform. In general, this will result in a smaller measured value for permeability compared to the case where feedback amplification is not used. Some suggest this to be the more precise method for permeability measurement, but the use of feedback amplification has prevented instruments such as the Soken from achieving ASTM acceptance to date.

Defining Terms

**Permeability:** The extent to which a material can be magnetized

**Hysteresis:** A ferromagnetic phenomenon in which the magnetic induction $B$ is out of phase with the magnetic driving force $H$.

50.4 Instrumentation

Michał Szyper
University of Mining and Metallurgy

Inductance is an electrical parameter that characterizes electric circuit elements (two- or four-terminal networks) that become magnetic field sources when current flows through them. They are called inductors, although inductance is not a unique property of them. Electric current \( i \) (A) and magnetic flux \( \Phi \) (Wb) are interdependent; that is, they are coupled. Inductance is a measurable parameter; therefore, it has a physical dimension, a measurement unit (the henry), as well as reference standards. Inductance is a property of all electrical conductors. It is found as self-inductance \( L \) of a single conductor and as mutual inductance \( M \) in the case of two or more conductors. Inductors can vary in construction, but windings in the form of coils are the most frequent. In this case, they have characteristic geometrical dimensions: surface \( A \), length \( l \), and \( N \) number of turns of windings. The path of magnetic flux can be specially shaped by magnetic cores. Figure 50.1 shows examples of different inductive elements of electric circuits.

Figures 50.1a and b present windings with self-inductance made as a coreless coil (a), and wound on a ferromagnetic core that is the concentrator of the magnetic field (b). A transformer loaded by impedance \( Z_L \) and an electromagnet loaded by impedance of eddy currents in the metal board, shown in Figures 50.1c and d, will have not only self-inductance of windings, but also mutual inductance between windings (c) or between winding and eddy currents (d). Self-inductances and mutual inductances can be detected in busbars of electric power stations as shown in Figure 50.1e, and also on tracks on printed circuit boards as in Figure 50.1f. Couplings between currents and electromagnetic fields can be made deliberately but can also be harmful, e.g., due to energy losses caused by eddy currents, or due to electromagnetic disturbances induced in the tracks of printed circuit boards. Inductors made as windings on ferromagnetic cores have numerous other applications.

The presence of a ferromagnetic core changes the shape of a magnetic field and increases inductance; but in the case of closed cores, it also causes nonlinear relations between inductance and current as well as current frequency. Closed magnetic cores then have a nonlinear and ambiguous magnetization characteristic \( \Phi (i) \) because of magnetic saturation and hysteresis. Inductances of open magnetic cores with an air gap are mainly dependent on the length of the magnetic path in the air. Real coils made of metal (e.g., copper) wire also show resistance \( R \). However, if resistance is measured at the coil terminals with ac current, it depends not only on the cross-section, length, and resistivity of the wire, but also on losses.
of active power in the magnetic core. These losses depend on both the current value and frequency. Resistances of inductive elements can also depend on the skin effect. This phenomenon consists of the flow of electric current through a layer of the conductor, near its outer surface, as the result of the effects of the conductor’s own magnetic field generated by the current flowing inside the conductor. Notice that the coils have also interturns and stray (to Earth) capacitances $C$. From its terminals, the inductive elements can then be described by impedances (two-terminal networks) or transmittances (four-terminal networks), values that are experimentally evaluated by current and voltage measurements, or by comparison them with reference impedances. The measured values and the equivalent circuit models of inductive elements are used for evaluation of model parameters: self-inductances, mutual inductances, resistances, and capacitances.

### 50.1 Definitions of Inductance

**Self-inductance** is defined as the relation between current $i$ flowing through the coil and voltage $v$ measured at its terminals [1].

\[
v = L \frac{di}{dt}
\]  

(50.1)

Using Equation 50.1, the unit of inductance, i.e., the henry, can be defined as follows:

One henry (1 H) is the inductance of a circuit in which an electromotive force of one volt (1 V) is induced, when the current in the circuit changes uniformly by one ampere (1 A) per second (1 s).

The definition of the unit implies the use of uniform-ramp current excitation (the derivative is constant); in practice, however, mainly sinusoidal current excitation is used in inductance measurement.

Mutual inductance $M$ of windings coupled by magnetic flux $\Phi$ is a parameter that depends on the coupling coefficient. The coupling coefficient is defined as *perfect coupling* in the case in which the total flux of one winding links the second one; *partial coupling* is the case in which only a fraction of flux links the second one; and *zero coupling* is the case in which no part of the flux of one winding links the second one. Assuming that, as in Figure 50.1c, the second $N$, winding is not loaded (i.e., $i_s = 0$) and the flux $\Phi$ is a part of the total flux produced by current $i_p$, then voltage $v_s$ is described by:
\[ \nu_s = N_s \frac{d\Phi}{dt} = \pm k \sqrt{L_p L_s} \frac{di_p}{dt} = \pm M \frac{di_s}{dt} \]

where \( \pm k \) is the coupling coefficient of the primary (p) and secondary (s) windings. Its sign depends on the direction of the windings. Because of the similarity between Equations 50.1 and 50.2, mutual inductance is defined similarly to self-inductance. The definitions of self-inductance and mutual inductance described above are correct when \( L \) and \( M \) can be assumed constant, i.e., not depending on current, frequency, or time.

### 50.2 Equivalent Circuits and Inductive Element Models

Equivalent circuits of inductive elements and their mathematical models are built on the basis of analysis of energy processes in the elements. They are as follows: energy storage in the parts of the circuits represented by lumped inductances (\( L \)) and capacitances (\( C \)), and dissipation of energy in the parts of the circuits represented by lumped resistances (\( R \)). Essentially, the above-mentioned energy processes are never lumped, so the equivalent circuits and mathematical models of inductive elements only approximate reality. Choosing an equivalent circuit (model), one can influence the quality of the approximation. In Figure 50.2, the basic models of typical coreless inductive elements of electric circuits are presented, using the type of inductance (self-inductance \( L \), mutual inductance \( M \)) and frequency band (low LF, high HF) as criteria. Models of inductive elements with ferromagnetic cores and problems concerning model parameter evaluation are beyond the scope of this chapter. The equivalent circuits of coreless inductive elements at low frequencies contain only inductances and series resistances. At high frequencies, parallel and coupling equivalent capacitances are included. Calculations of \( LCR \) values of complicated equivalent circuits (with many \( LCR \) elements) are very tedious, so often for that purpose a special dedicated processor with appropriate software is provided in the measuring device.

In metrology, complex notation [1] is frequently used to describe linear models of inductive elements. In complex notation, the impedances and transmittances are as follows:
The components of impedances and transmittances can be described as algebraic functions of the LCR elements determined for the equivalent circuit. In each case, the forms of the functions depend on the assumed equivalent circuit. By measuring the real and imaginary components or modules and phase angles of impedances or transmittances and comparing them to corresponding quantities determined for the equivalent circuit, and then solving the obtained algebraic equations, the LCR values of the equivalent circuit can be determined.

An example for the LF equivalent circuit in Figure 50.2 can be obtained:

\[
Z = R_z + j X_z = Z_m \exp \left( j \phi_z \right), \quad Z_m = \sqrt{R_z^2 + X_z^2}, \quad \phi_z = \arctan \frac{X_z}{R_z} \tag{50.3}
\]

\[
T = R_t + j X_t = T_m \exp \left( j \phi_t \right), \quad T_m = \sqrt{R_t^2 + X_t^2}, \quad \phi_t = \arctan \frac{X_t}{R_t} \tag{50.4}
\]

The components of impedances and transmittances can be described as algebraic functions of the LCR elements determined for the equivalent circuit. In each case, the forms of the functions depend on the assumed equivalent circuit. By measuring the real and imaginary components or modules and phase angles of impedances or transmittances and comparing them to corresponding quantities determined for the equivalent circuit, and then solving the obtained algebraic equations, the LCR values of the equivalent circuit can be determined.

An example for the LF equivalent circuit in Figure 50.2 can be obtained:

\[
Z = R + j \omega L = R_z + j X_z \rightarrow R = R_z, \quad \omega L = X_z \tag{50.5}
\]

\[
T = j \omega M = R_t + j X_t \rightarrow R_t = 0, \quad \omega M = X_t \tag{50.6}
\]

For the HF equivalent circuits shown in Figure 50.2, the models are more complex. More particularly, models of circuits with mutual inductance can represent:

- Ideal transformers, with only their self-inductances and mutual inductances of the coils
- Perfect transformers, without losses in the core
- Real transformers, having a specific inductance, resistance, and capacity of the coils, and also a certain level of losses in the core

The quality factor \( Q \) and dissipation factor \( D \) are defined for the equivalent circuits of inductive elements. In the case of a circuit with inductance and resistance only, they can be defined as follows:

\[
Q = \frac{\omega L}{R} = \frac{\omega}{\tau} \tag{50.7}
\]

where parameter \( \tau \) is a time constant.

The presented models with lumped inductance are not always a sufficiently good approximation of the real properties of electric circuits. This particularly applies to circuits made with geometrically large wires (i.e., of a significant length, surface area, or volume). In such cases, the models applied use an adequately distributed inductance (linearly, over the surface, or throughout the volume). Inductances determined to be the coefficients of such models depend on the geometrical dimensions and, in the case of surface conductivity or conduction by the surface or volume, by the frequencies of the currents flowing in the conductor lines.

A complex formulation is used to represent and analyze circuits with lumped and linear inductances. Sometimes the same thing can be done using simple linear differential equations or the corresponding integral operators.

The analytical methodology for such circuits is described in [1]. In the case of nonlinear inductances, the most frequently used method is the linearized equivalent circuit, also represented in a simplified form using a complex formulation. Circuits with distributed inductance are represented by partial differential equations.
50.3 Measurement Methods

Impedance (or transmittance) measurement methods for inductors are divided into three basic groups:

2. Bridge and differential methods based on comparison of the voltages and currents of the measured and reference impedances until a state of balance is reached.
3. Resonance methods based on physical connection of the measured inductor and a capacitor to create a resonant system.

Current–Voltage Methods

Current–voltage measurement methods are used for all types of inductors. A current–voltage method using vector voltmeters is shown in Figure 50.3. It is based on evaluation of the modules and phase angles of impedances (in the case of self-inductance) or transmittances (in the case of mutual inductance) using Equations 50.8 and 50.9

\[
Z = \frac{v_1}{i} = R_i \frac{v_2}{v_1} = R_i \frac{V_m \exp(j\phi_2)}{V_{m1} \exp(j\phi_1)} = R_i \frac{V_{m2} \exp(j\phi_2 - \phi_1)}{V_{m1} \exp(j\phi_1)} = Z_m \exp(j\phi_z) \tag{50.8}
\]

\[
T = \frac{v_s}{i_p} = R_i \frac{v_{pr}}{v_s} = R_i \frac{V_m \exp(j\phi_1)}{V_{mpr} \exp(j\phi_{pr})} = R_i \frac{V_{ms} \exp(j\phi_s - \phi_{pr})}{V_{mpr} \exp(j\phi_{pr})} = T_m \exp(j\phi_1) \tag{50.9}
\]

where
- \(R_i\) = Sampling resistor used for measurement of current
- \(v_1\) = Voltage proportional to the current
- \(v_2\) = Voltage across the measured impedance
- \(v_{pr}\) = Voltage proportional to primary current
- \(v_s\) = Voltage of the secondary winding of the circuit with mutual inductance

A block diagram illustrating the principle of the vector voltmeter is shown in Figure 50.4a. The system consists of the multiplier or gated synchronous phase-sensitive detector (PSD) [3, 4] of the measured...
voltage \( v \) with the switching system of the phase of the reference voltage \( v_{dn} \), integrator, digital voltmeter, and processor. The principle of vector voltmeter operation is based on determination of the magnitude \( V_m \) and phase angle \( \phi \) of the measured voltage \( v \) in reference to voltage \( v_1 \), which is proportional to the current \( i \). Assume that voltages \( v \) and \( v_{dn} \) are in the following forms:

\[
v(t) = V_m \sin(\omega t + \phi) = V_m \left( \sin \omega t \cos \phi + \cos \omega t \sin \phi \right)
\]

(50.10)

\[
v_{dn}(t) = V_{md} \sin \left( \omega t + \frac{n \pi}{2} \right), \quad n = 0,1,2,3
\]

(50.11)

Phase angle \( n \pi/2 \) of voltage \( v_{dn} \) can take values from the set \( \{0, \pi/2, \pi, 3/2 \pi \} \) by choosing the number \( n \) that gives the possibility of detecting the phase angle \( \phi \) in all four quadrants of the Cartesian coordinate system, as is shown in Figure 50.4b. A multiplying synchronous phase detector multiplies voltages \( v \) and \( v_{dn} \) and bilinearly, and the integrator averages the multiplication result during time \( T_i \).

\[
V_{in} = \frac{1}{T_i} \int_0^{T_i} v v_{dn} \, dt
\]

(50.12)

Averaging time \( T_i = k T_i \), \( k = 1,2,3 \ldots \) is a multiple of the period \( T \) of the measured voltage. From Equations 50.10 through 50.12, an example for \( 0 \leq \phi \leq \pi/2 \) (e.g., \( n = 0 \) and \( n = 1 \)), a pair of numbers is obtained:

\[
V_{i0} = 0.5 V_m V_{md} \cos \phi, \quad V_{i1} = 0.5 V_m V_{md} \sin \phi
\]

(50.13)

which are the values of the Cartesian coordinates of the measured voltage \( v \). The module and phase angle of voltage are calculated from:

\[
V = \frac{2}{V_{md}} \sqrt{V_{i0}^2 + V_{i1}^2}, \quad \phi = \arctan \frac{V_{i1}}{V_{i0}}
\]

(50.14)

Both coordinates of the measured voltage \( v \) can be calculated in a similar way in the remaining quadrants of the Cartesian coordinate system. A vector voltmeter determines the measured voltage as vector (phasor) by measurement of its magnitude and angle as shown in Figure 50.4.
The current and voltage method of impedance or transmittance measurement is based on measurement of voltages \( v_1 = i R_r \) and \( v_2 = i R_r \) and the use of Equations 50.8 or 50.9. Calculation of the voltage measurement results and control of number \( n \) is performed by a processor. References [11–13] contain examples of PSD and vector voltmeter applications. Errors of module and phase angle measurement of impedance when using vector voltmeters are described in [11] as being within the range of 1% to 10% and between \( 10^{-5} \text{ rad} \) and \( 10^{-3} \text{ rad} \), respectively, for a frequency equal to 1.8 GHz. Publications [9] and [10] contain descriptions of applications of comparative methods which have had an important influence on the development of the methods.

Another method of comparative current/voltage type is a modernized version of the “three-voltmeter” method [7]. A diagram of a measurement system illustrating the principle of the method is shown in Figure 50.5a and b.

The method is based on the properties of an operational amplifier (OA), in which output voltage \( v_2 \) is proportional to input voltage \( v_1 \) and to the ratio of the reference resistance \( R_r \) to measured impedance \( Z \).

The phasor difference \( v_3 \) of voltages \( v_1 \) and \( v_2 \) can be obtained using the differential amplifier (DA). The three voltages (as in Figure 50.5b) can be used for the module \( Z_m \) and phase \( \phi \) calculation using relations:

\[
\begin{align*}
  v_2 &= -R_y = -\frac{R_r}{Z} v_1 \rightarrow Z_m = \frac{V_2}{V_1} R_r \quad (50.15) \\
  v_3 &= v_1 - v_2 \rightarrow \phi = \arccos \frac{V_3^2 + V_2^2 - V_1^2}{2 V_1 V_2} \quad (50.16)
\end{align*}
\]

where \( V_1, V_2, V_3 \) are the results of rms voltage measurements in the circuit. The advantage of the method lies in limiting the influence of stray capacitances as a result of attaching one of the terminals of the measured impedance to a point of “virtual ground.” However, to obtain small measurement errors, especially at high frequencies, amplifiers with very good dynamic properties must be used.

Joint errors of inductance measurement, obtained by current and voltage methods, depend on the following factors: voltmeter errors, errors in calculating resistance \( R_r \), system factors (residual and leakage inductances, resistances and capacitances), and the quality of approximation of the measured impedances by the equivalent circuit.
Bridge Methods

There is a variety of bridge methods for measuring inductances. Bridge principles of operation and their circuit diagrams are described in [2–5] and [7]. The most common ac bridges for inductance measurements and the formulae for calculating measurement results are shown in Figure 50.6.

The procedure referred to as bridge balancing is based on a proper selection of the reference values of the bridge so as to reduce the differential voltage to zero (as referred to the output signal of the balance indicator). It can be done manually or automatically.

FIGURE 50.6 Bridge circuits used for inductance measurements: Maxwell-Wien bridge (a), Hay bridge (b), Carey-Foster bridge (c), and ac bridge with Wagner branch (d). Block abbreviations: “Osc” — oscillator, “Amp” — amplifier, “Det” — amplitude detector.
The condition of the balanced bridge \( v_0 = 0 \) leads to the following relation between the impedances of the bridge branches; one of them (e.g., \( Z_l \)) is the measured impedance:

\[
Z_1 Z_3 = Z_2 Z_4 \rightarrow \left( R_l + j X_l \right) \left( R_1 + j X_1 \right) = \left( R_2 + j X_2 \right) \left( R_4 + j X_4 \right)
\]  

(50.17)

Putting Equation 50.17 into complex form and using expressions for the impedances of each branch, two algebraic equations are obtained by comparing the real and imaginary components. They are used to determine the values of the equivalent circuit elements of the measured impedance. In the most simple case, they are \( L \) and \( R \) elements connected in series. More complicated equivalent circuits need more equations to determine the equivalent circuit parameters. Additional equations can be obtained from measurements made at different frequencies.

In self-balancing bridges, vector voltmeters preceded by an amplifier of the out-of-balance voltage \( v_0 \) are used as “zero” detectors. The detector output is coupled with variable standard bridge components. The Maxwell-Wien bridge shown in Figure 50.6a is one of the most popular ac bridges. Its range of measurement values is large and the relative error of measurement is about 0.1% of the measured value. It is used in the wide-frequency band 20 Hz to 1 MHz. The bridge is balanced by varying the \( R_2 \) and \( R_3 \) resistors or by varying \( R_5 \) and capacitor \( C_3 \). Some difficulties can be expected when balancing a bridge with inductors with high time constants.

The Hay bridge presented in Figure 50.6b is also used for measurement of inductors, particularly those with high time constants. The balance conditions of the bridge depend on the frequency value, so the frequency should be kept constant during the measurements, and the bridge supply voltage should be free from higher harmonic distortions. The dependence of bridge balance conditions on frequency also limits the measurement ranges. The bridge is balanced by varying \( R_3 \) and \( R_4 \) resistors and by switching capacitor \( C_3 \).

Mutual inductance \( M \) of two windings with self-inductances \( L_p \) and \( L_s \) can be determined by Maxwell-Wien or Hay bridges. For this, two inductance measurements have to be made for two possible combinations of the series connection of both coupled windings: one of them for the corresponding directions of the windings, and one for the opposite directions. Two values of inductances \( L_1 \) and \( L_2 \) are obtained as the result of the measurements:

\[
L_1 = L_p + L_s + 2 M, \quad L_2 = L_p + L_s - 2 M
\]  

(50.18)

Mutual inductance is calculated from:

\[
M = 0.25 \left( L_1 - L_2 \right)
\]  

(50.19)

The Carey-Foster bridge described in Figure 50.6c is used for mutual inductance measurement. The self-inductances of the primary and secondary windings can be determined by two consecutive measurements. The expressions presented in Figure 50.6c yield the magnetic coupling coefficient \( k \). The bridge can be used in a wide frequency range. The bridge can be balanced by varying \( R_1 \) and \( R_4 \) resistances and switching the remaining elements.

For correct measurements when using ac bridges, it is essential to minimize the influence of harmful couplings among the bridge elements and connection wires, between each other and the environment. Elimination of parallel (common) and series (normal) voltage distortions is necessary for high measurement resolution. These couplings are produced by the capacitances, inductances, and parasitic resistances of bridge elements to the environment and among themselves. Because of their appearance, they are called stray couplings. Series voltage distortions are induced in the bridge circuit by varying common electromagnetic fields. Parallel voltage distortions are caused by potential differences between the reference point of the supply voltage and the points of the out-of-balance voltage detector system.
Magnetic shields applied to connection wires and bridge-balancing elements are the basic means of minimizing the influence of parasitic couplings and voltage distortions [8]. All the shields should be connected as a “star” connection; that is, at one point, and connected to one reference (“ground”) point of the system. For these reasons, amplifiers of out-of-balance voltage with symmetric inputs are frequently used in ac bridges, as they reject parallel voltage distortions well.

When each of the four nodes of the bridge has different stray impedances to the reference ground, an additional circuit called a Wagner branch is used (see Figure 50.6). By varying impedances $Z_5$ and $Z_6$ in the Wagner branch, voltage $v_c$ can be reduced to zero; by varying the other impedances, voltage $v_0$ can also be reduced to zero. In this way, the bridge becomes symmetrical in relation to the reference ground point and the influence of the stray impedances is minimized.

The joint error of the inductance measurement results (when using bridge methods) depends on the following factors: the accuracy of the standards used as the bridge elements, mainly standard resistors and capacitors; errors of determining the frequency of the bridge supplying voltage (if it appears in the expressions for the measured values); errors of the resolution of the zero detection systems (errors of state of balance); errors caused by the influence of residual and stray inductances; resistances and capacitances of the bridge elements and wiring; and the quality of approximation of the measured impedances in the equivalent circuit.

The errors of equivalent resistance measurements of inductive elements using bridge methods are higher than the errors of inductance measurements. The number of various existing ac bridge systems is very high. Often the bridge system is built as a universal system that can be configured for different applications by switching elements. One of the designs of such a system is described in [3]. Reference [13] describes the design of an automatic bridge that contains, as a balancing element, a multiplying digital-to-analog converter (DAC), controlled by a microcontroller.

**Differential Methods**

Differential methods [7] can be used to build fully automatic digital impedance meters (of real and imaginary components or module and phase components) that can also measure inductive impedances. Differential methods of measurement are characterized by small errors, high resolution, and a wide frequency band, and often utilize precise digital control and digital processing of the measurement results. The principle of differential methods is presented through the example of a measuring system with an inductive voltage divider and a magnetic current comparator (Figure 50.7). An inductive voltage divider (IVD) is a precise voltage transformer with several secondary winding taps that can be used to vary the secondary voltage in precisely known steps [7]. By combining several IVDs in parallel, it is possible to obtain a precise voltage division, usually in the decade system. The primary winding is supplied from a sinusoidal voltage source. A magnetic current comparator (MCC) is a precise differential transformer with two primary windings and a single secondary winding. The primary windings are connected in a differential way; that is, the magnetic fluxes produced by the currents in these windings subtract. The output voltage of the secondary winding depends on the current difference in the primary windings. MCCs are characterized by very high resolution and low error but are expensive. In systems in common use, precise control of voltages (IVD) is provided by digitally controlled (sign and values) digital voltage dividers (DVD), and the magnetic comparator is replaced by a differential amplifier.

The algorithms that enable calculation of $L$ and $R$ element values of the series equivalent circuit of an inductive impedance $Z$ in a digital processor result from the mathematical model described in Figure 50.7. When the system is in a state of equilibrium, the following relations occur:

$$v_0 = 0 \rightarrow i_2 - i_1 = 0 \quad (50.20)$$

$$i_2 = v_0 \frac{1}{R + j\omega L}, \quad i_1 = D_i v_i \left( \frac{b}{R_i} - a j\omega C_i \right) \quad (50.21)$$
where $0 < D_r \leq 1$ is the coefficient of $v_1$, voltage division and the values $a$ and $b$ are equivalent to the binary signals used by the processor to control DVD. Multiple digital-to-analog converters (DACs) are used as digitally controlled voltage dividers. They multiply voltage $D_r v_1$ by negative numbers ($-a$, $-b$), which is needed in the case of using a standard capacitor $C_r$ for measurements of inductance. After substituting Equation 50.21 into Equation 50.20 and equating the real and imaginary parts, the following formulae are obtained:

$$L = \frac{a R_i^2 C_i}{D_r \left( b^2 + a^2 \omega^2 R_i^2 C_i \right)} \quad (50.22)$$

$$R = \frac{b R_i}{D_r \left( b^2 + a^2 \omega^2 R_i^2 C_i \right)} \quad (50.23)$$

The lengths $N$ of the code words $\{a_n\} \leftrightarrow a$ and $\{b_n\} \leftrightarrow b, n = 1, 2, \ldots, N$ determine the range and resolution of the measurement system; that is, the highest measurable inductance and resistance values and the lowest detectable values. The range can be chosen automatically by changing the division coefficients $D_r$. Achieved accuracy is better than 0.1% in a very large range of impedances and in a sufficiently large frequency range. Measurements can be periodically repeated and their results can be stored and processed.

**Resonance Methods**

Resonance methods are a third type of inductance measurement method. They are based on application of a series or parallel resonance $LC$ circuits as elements of either a bridge circuit or a two-port (four-terminal) “T”-type network. Examples of both circuit applications are presented in Figure 50.8.

In the bridge circuit shown in Figure 50.8a, which contains a series resonance circuit, the resonance state is obtained by varying the capacitor $C_r$, and then the bridge is balanced ($v_b = 0$) using the bridge resistors. From the resonance and balance conditions, the following expressions are obtained:
To calculate the values of the LR elements of the series equivalent circuit of the measured impedance, it is necessary to measure (or know) the angular frequency \( \omega \) of the supply voltage. The frequency band is limited by the influence of unknown interturn capacitance value. In the “shunted T” network presented in Figure 50.8b, the state of balance (i.e., the minimal voltage \( v_0 \) value) is achieved by tuning the multiloop LCR circuit to parallel resonance. The circuit analysis [7] is based on the “star-delta” transformation of the \( C_r R C_r \) element loop and leads to the relations for \( L \) and \( R \) values:

\[
L = \frac{1}{\omega^2 C_r}, \quad R = R_2 \frac{R_4}{R_3} \tag{50.24}
\]

To calculate the values of the LR elements of the series equivalent circuit of the measured impedance, it is necessary to measure (or know) the angular frequency \( \omega \) of the supply voltage. The frequency band is limited by the influence of unknown interturn capacitance value. In the “shunted T” network presented in Figure 50.8b, the state of balance (i.e., the minimal voltage \( v_0 \) value) is achieved by tuning the multiloop LCR circuit to parallel resonance. The circuit analysis [7] is based on the “star-delta” transformation of the \( C_r R C_r \) element loop and leads to the relations for \( L \) and \( R \) values:

\[
L = \frac{2}{\omega^2 C_r}, \quad R = \frac{1}{\omega^2 C_r^2 R_i} \tag{50.25}
\]

According to reference [7], a “double T” network can be used for inductive impedance measurements at high frequencies (up to 100 MHz).

### 50.4 Instrumentation

Instruments commonly used for inductance measurements are built as universal and multifunctional devices. They enable automatic (triggered or cyclic) measurements of other parameters of the inductive elements: capacitance, resistance, quality, and dissipation factors. Equipped with interfaces, they can also work in digital measuring systems. Table 50.1 contains a review of the basic features of the instruments called LCR meters, specified on the basis of data accessible from the Internet [15]. Proper design of LCR meters limits the influence of the factors causing errors of measurement (i.e., stray couplings and distortions). The results of inductance measurements also depend on how the measurements are performed, including how the measured inductor is connected to the meter. Care should be taken to limit such influences as inductive and capacitive couplings of the inductive element to the environment, sources of distortion, and the choice of operating frequency.

Electronic circuits consist of numerous elements that can be lumped, distributed, or a combination of both. The components are regarded as **lumped** if their size is much smaller than the signal wavelength. This condition holds for resistors, inductors, capacitors, transformers, diodes, transistors, or similar devices operating in printed circuits at frequencies up to a few hundred megahertz or even higher in small integrated circuits. In the microwave or millimeter-wave region, the elements and their connecting transmission lines must be considered as **distributed**. While in lumped circuits a change of voltage or current at one single point immediately affects these quantities at all other points, in distributed circuits the propagation properties now have to be taken into account. The same holds for long connecting cables even at lower frequencies.

To describe the effect of any element within an electronic circuit or of the connection of different circuits, the **immittance** is used as a characteristic quantity. It simply provides a relation of sinusoidal voltage and current at the terminals of the element as a function of frequency. The immittance therefore also characterizes arbitrarily complicated networks considered as one port. This is useful, since in practice the single elements are interconnected to networks. On the other hand, the elements themselves are not ideal. A resistor, for example, made of wound resistive wire, has parasitic components such as capacitance and inductance of winding and terminals. It must be represented by an equivalent circuit forming a complex network [1].

The word “immittance” was proposed by Bode [2] and is a combination of the words “impedance” and the reverse quantity called “admittance.” These terms do not only occur in electrodynamics but wherever wave propagation takes place — in acoustics as well as in elasticity. The emphasis of this chapter is on lumped networks and guided electromagnetic waves. Readers interested in more general propagation and scattering phenomena are referred to [3].
51.1 Definitions

Assume a stable linear and time-invariant (LTI) network with only one port. Linearity and time-independence are generally met for combinations of passive elements but also for active devices with small-signal driving under constant physical conditions (temperature, humidity, dimensions, etc.). In the steady state, a voltage \( v(t) = V_m \cos(\omega t + \phi_v) \) with amplitude \( V_m \) varying harmonically with the angular frequency \( \omega = 2\pi f \) which is applied to the terminal then only produces voltages and currents of the same frequency within the network (Figure 51.1). Using complex notation:

\[
\begin{align*}
    v(t) &= \text{Re}\{V e^{j\omega t}\} & V &= V_m e^{j\phi_v} \\
    i(t) &= I_m \cos(\omega t + \phi_i) &= \text{Re}\{I e^{j\omega t}\} & I &= I_m e^{j\phi_i}
\end{align*}
\]  

(51.1)

the current flowing into the network is given by:

\[
\begin{align*}
    v(t) &= \text{Re}\{V e^{j\omega t}\} & V &= V_m e^{j\phi_v} \\
    i(t) &= I_m \cos(\omega t + \phi_i) &= \text{Re}\{I e^{j\omega t}\} & I &= I_m e^{j\phi_i}
\end{align*}
\]

(51.2)

The phasors \( V \) and \( I \) are time independent and can be represented in the complex plane (Figure 51.2). Relating voltage and current at the terminal, the network is uniquely described by means of a complex frequency-dependent quantity, the impedance \( Z \):

\[
Z = \frac{V}{I} = \frac{V_m e^{j(\phi_v - \phi_i)}}{I_m} = |Z| e^{j\phi_z}
\]

(51.3)
For a given frequency, an arbitrarily complex network within a circuit thus can be replaced by a single element without changing the electrical properties at the terminals. Sometimes it is more convenient to use the inverse of $Z$, the admittance $Y$:

$$Y = \frac{1}{Z} = \frac{I}{V} = |Y|e^{j\phi} \quad \text{with} \quad \phi_y = \phi_z = -\phi \tag{51.4}$$

Both quantities are combined to form the word “immittance.” Figure 51.3 shows their representation in the complex plane. Equations 51.3 and 51.4 give the definition in polar coordinates. In data sheets, they are often written as:

$$|Z| \angle \phi_z, \quad |Y| \angle \phi_y \tag{51.5}$$

Using Euler’s identity $e^{j\phi} = \cos \phi + j \sin \phi$, one obtains in rectangular coordinates:

$$Z = |Z|e^{j\phi_z} = |Z| \cos \phi_z + j|Z| \sin \phi_z = R + jX \tag{51.6}$$

$$Y = |Y|e^{j\phi_y} = |Y| \cos \phi_y + j|Y| \sin \phi_y = G + jB$$

From Figure 51.3, the following relations between rectangular and polar coordinate representation can be deduced immediately:

$$R = |Z| \cos \phi_z = |Z| = \sqrt{R^2 + X^2} \quad G = |Y| \cos \phi_y = |Y| = \sqrt{G^2 + B^2}$$

$$X = |Z| \sin \phi_z \quad \phi_z = \tan^{-1} \left( \frac{X}{R} \right) \quad B = |Y| \sin \phi_y \quad \phi_y = \tan^{-1} \left( \frac{B}{G} \right) \tag{51.7}$$
The real parts are the resistance $R$ and the conductance $G$. They indicate the losses within the network. The imaginary parts, which are termed reactance $X$ and susceptance $B$, respectively, are a measure of the reactive energy stored in the network during one period. In general, all these quantities are frequency dependent.

Note that the correct sign of the imaginary parts must be used: the angle $\varphi$ is in the range of $-180^\circ < \varphi \leq 180^\circ$ and $\varphi < 0$ always corresponds to $X, B < 0$.

For elements with low losses, the loss angle $\delta$ or loss factor $D$ are often given instead of the phases $\varphi_x$ and $\varphi_y$. They are always positive small quantities and tend to 0 for a lossless device.

$$D = \tan \delta = \tan \left( \frac{\pi}{2} - |\varphi| \right) = \tan \left( \frac{\pi}{2} - |\varphi_0| \right) = \left| \frac{R}{X} \right| = \left| \frac{G}{B} \right|$$  \hspace{1cm} (51.8)

The inverse quantity is the quality factor $Q = 1/D$. It involves a ratio of stored electric energy to power dissipated. A high $Q$ indicates a nearly pure reactive component.

In high-power electronics, it is necessary to reduce losses on transmission lines and therefore avoid currents associated with reactive load components. To obtain a criterion for the application and efficiency of compensation techniques, a power factor is defined. From complex power representation:

$$P = VI^* = |P| \left( \cos \varphi + j \sin \varphi \right)$$  \hspace{1cm} (51.9)

(the asterisk indicates the conjugate complex number) follows from Equations 51.3 and 51.4.

$$P = |I| |Z| \left( \cos \varphi_x + j \sin \varphi_x \right) = |V| |Y^*| \left( \cos \varphi_y - j \sin \varphi_y \right)$$  \hspace{1cm} (51.10)

and since the effective power is given by the real part of $P$:

$$P_{\text{eff}} = \Re \{P\} = |P| \cos \varphi$$  \hspace{1cm} (51.11)

the power factor is:

$$\cos \varphi = \cos \varphi_x = \cos \varphi_y$$  \hspace{1cm} (51.12)

In general, rms values are used for the phasors. Otherwise, a factor 1/2 has to be taken into account in Equations 51.9 and 51.10, since $|P| = \frac{1}{2} V_{\text{rms}} I_{\text{rms}}$ for sinusoidal quantities.

It can also be seen from Equations 51.9 and 51.10 that the immittances are directly related to the apparent power:

$$|P| = |V| |I| = |I^*| |Z^*| = |V^*| |Y^*|$$  \hspace{1cm} (51.13)

### 51.2 Ideal Lumped Components

The immittances of the fundamental passive circuit elements are derived from their instantaneous voltage current relations using Equations 51.1 through 51.4 and the differentiation rules.
Resistances
From Equation 51.14:

\[ v(t) = R i(t) \]  

(51.14)

it follows \( V = RI \) and thus \( Z = R \) or \( Y = G \). The immittance of a resistance is real and identical to its dc resistance or conductance.

Inductances
Voltage and current are related via the differential equation:

\[ v(t) = L \frac{d i(t)}{d t} \]  

(51.15)

with inductance \( L \), from which follows that \( V = j \omega LI \) and

\[ Z = j \omega L = j X_L, \quad Y = \frac{1}{j \omega L} = -j \frac{1}{X_L} = -j B_L \]  

(51.16)

Capacitances
From Equation 51.17:

\[ i(t) = C \frac{d v(t)}{d t} \]  

(51.17)

with capacitance \( C \), it follows that \( I = j \omega CV \) and

\[ Y = j \omega C = j B_C, \quad Z = \frac{1}{j \omega C} = -j \frac{1}{B_C} = -j X_C \]  

(51.18)

The immittance of ideal inductors and capacitors is purely imaginary with different signs according to the phase shift of \( \pm 90^\circ \) between voltage and current. A general element or network is therefore called inductive or capacitive at a given frequency corresponding to the sign of the imaginary part of its impedance. Note, however, that the frequency dependence can be much more complicated than for these ideal elements and the impedance can even change several times between capacitive and inductive characteristic.

51.3 Distributed Elements
At high frequencies, the size of the elements may no longer be small compared to the signal wavelength. Propagation effects must then be taken into account and the components can no longer be described by means of simple lumped equivalent circuits. If at all possible, they are replaced by transmission line circuits, which are easier to characterize; they realize the required electrical properties more exactly within a defined frequency range.
Assuming a simplifying transverse electromagnetic wave (TEM) mode with no field components in the propagation direction, voltages and currents can be uniquely defined and are given as solutions of the corresponding wave equations [4]:

\[
\frac{d^2 V}{dz^2} - \gamma^2 V = 0, \quad \frac{d^2 I}{dz^2} - \gamma^2 I = 0 \tag{51.19}
\]

They vary along the line in the \(z\)-direction according to:

\[
V(z) = V_0^+ e^{-\gamma z} + V_0^- e^{\gamma z}, \quad I(z) = I_0^+ e^{-\gamma z} + I_0^- e^{\gamma z} \tag{51.20}
\]

These solutions are sums of forward \((e^{-\gamma z})\) and backward \((e^{\gamma z})\) traveling waves with amplitudes \(V_0^+, I_0^+\) and \(V_0^-, I_0^-\) and a propagation constant:

\[
\gamma = \sqrt{\left(R' + j\omega L'\right)\left(G' + j\omega C'\right)} \tag{51.21}
\]

The equivalent circuit of the transmission line is shown in Figure 51.4. The energy storage in the electric field is accounted for by the distributed shunt capacitance \(C'\) per unit length, while the effect of the magnetic field is represented by the series inductance \(L'\) per unit length. The series resistance \(R'\) per unit length and the shunt conductance \(G'\) per unit length represent the power losses in the conductors and in the dielectric, respectively. The amplitudes of voltage and current are related by means of the characteristic impedance \(Z_o\):

\[
Z_o = \frac{V}{I} = \frac{V^+ - V^-}{I^+ - I^-} = \sqrt{\frac{R' + j\omega L'}{G' + j\omega C'}} \tag{51.22}
\]

Of special interest for the use within a network is the input impedance \(Z_l\) of the transmission line. It depends also on the termination \(Z_t\) at the other end of the line. For a transmission line of length \(l\), it is given by:

\[
Z_l = Z_o \frac{Z_t + Z_o \tanh \gamma l}{Z_o + Z_t \tanh \gamma l} \tag{51.23}
\]

that is, a transmission line transforms the impedance \(Z_t\) into \(Z_l\) at the input.
A quantity more suitable to wave propagation and measurement at high frequencies is the reflection coefficient $\Gamma$. It is defined by the relation of the voltages associated with forward and backward traveling waves. At the end of the line, using $V(l) = Z_L I(l)$, one finds:

$$\Gamma = \frac{V_0 e^{j\gamma l}}{V_0^* e^{-j\gamma l}} = \frac{Z_L - Z_0}{Z_L + Z_0}$$  \hspace{1cm} (51.24)

For devices that support quasi or strong non-TEM waves like microstrip lines, hollow waveguides, dielectric and optical waveguides, a voltage cannot be uniquely defined. That is why several definitions of the characteristic impedance $Z_0$ exist [5].

### 51.4 Interconnections and Graphical Representations

Since Kirchhoff’s laws for voltages and currents also holds for complex quantities, the rules for series and parallel connections of resistances and susceptances in the dc case apply as well for immittances.

**Series connection:**

$$Z = \sum_i Z_i \quad \frac{1}{Y} = \sum_i \frac{1}{Y_i}$$  \hspace{1cm} (51.25)

**Parallel connection:**

$$Y = \sum_i Y_i \quad \frac{1}{Z} = \sum_i \frac{1}{Z_i}$$  \hspace{1cm} (51.26)

As an example, consider a simplified equivalent circuit of a resistor with the nominal value $R_0$ (Figure 51.5). Gradually using the rules for series and parallel connection and the impedances for inductances (Equation 51.16) and capacitances (Equation 51.18), the impedance of the real resistor with parasitic elements as given leads to:

$$Z = \frac{R_0 + j\omega L}{1 - \omega^2 LC + j\omega R_0}$$  \hspace{1cm} (51.27)

The magnitude and phase of $Z/R_0$ as a function of $\omega/\omega_0$ are shown in Figure 51.6 with $\omega_0 = 1/\sqrt{LC}$ as the resonant frequency defined by the parasitic elements, which might be caused by the windings of a wire-wound resistor. The network is inductive for low ($\varphi_\omega > 0$) and capacitive for high frequencies. An
alternative representation is to plot real and imaginary parts in the impedance plane with the frequency as parameter as indicated by the labels (Figure 51.7). This version, called the locus, is very suitable to see immittance changes caused by parameters like frequency or adjustable elements within the network. Note that both real and imaginary parts are parameter dependent and vary with frequency.

**FIGURE 51.6** Normalized magnitude (a) and phase (b) of the impedance of a wire-wound resistor varying with frequency. $\omega_0$ is the resonant frequency defined by the parasitic elements.
In high-frequency applications, one obtains the impedance more easily from the reflection coefficient. Rewriting Equation 51.24 in the form:

\[ \Gamma = \frac{Z_L - 1}{Z_L + 1} \quad \text{with} \quad Z_L = \frac{Z_L}{Z_0} \]  

(51.28)

defines a transformation of which the graphical representation has been called the Smith chart (Figure 51.8). It can be regarded as two coordinate systems lying one on top of the other. The reflection coefficient is given in polar coordinates around the center, the circles give the real and imaginary part of the associated impedance. The Smith chart is very useful for solving transmission line and waveguide impedance matching problems [6].

### 51.5 Measurement Techniques

Since immitances are complex quantities, one must determine two parameters: magnitude and phase or real and imaginary part, described as vector measurements. There exist several techniques depending on frequency range and required accuracy [7].

#### Current–Voltage Methods

A simple way to measure immitances follows directly from the defining Equation 51.3. Applying a well-known sinusoidal voltage to the terminal and measuring magnitude and phase of the current gives the
desired quantity (Figure 51.1). However, the internal impedance $Z_A$ of the ammeter should be known exactly and the unknown impedance is then given by:

$$Z = \frac{V}{I} - Z_A$$  \hspace{1cm} (51.29)$$

In practical applications, impedances below 1000 Ω are measured by passing a predetermined current through the unknown device and measuring the voltage across it. Phase angle information is obtained by comparing the relative phase between voltage and current by means of a phase detector [8].

A variant on this method using only the better practicable voltage measurements is shown in Figure 51.9. The accurately known resistor $R$ must be small compared to $Z_x$ and to the internal resistance of $V_2$. One finds that:

$$Z_x = \left(\frac{V}{V_2} - 1\right)R, \quad \text{or} \quad Z_x = \frac{V}{V_2}R \quad \text{if} \quad R \ll |Z_x|$$  \hspace{1cm} (51.30)$$

The measurement can be enhanced using an operational amplifier with high input and low output resistance in an inverting circuit (Figure 51.10). The unknown is then given by
Practical implementations use operational amplifiers as part of an autobalancing bridge; see [7, 8].

Bridge Methods

Alternating current bridges are low-cost standard laboratory devices to measure impedances over a wide frequency range from dc up to 300 MHz with very high precision (Figure 51.11). A comprehensive survey is given in [1]. Their main advantage is that only a zero indicator in the diagonal branch is necessary. For this reason, the internal impedance does not influence the accuracy and the null point can be detected with a high sensitivity ac galvanometer as well as with headphones in the audio frequency range.

If the bridge is balanced, the unknown immittance is given by:

\[ Z_x = \frac{V_x}{V_2} R \]  

(51.31)

Practical implementations use operational amplifiers as part of an autobalancing bridge; see [7, 8].

Bridge Methods

Alternating current bridges are low-cost standard laboratory devices to measure impedances over a wide frequency range from dc up to 300 MHz with very high precision (Figure 51.11). A comprehensive survey is given in [1]. Their main advantage is that only a zero indicator in the diagonal branch is necessary. For this reason, the internal impedance does not influence the accuracy and the null point can be detected with a high sensitivity ac galvanometer as well as with headphones in the audio frequency range.

If the bridge is balanced, the unknown immittance is given by:

\[ Z_x = \frac{Z_1 Z_2}{Z_3} \text{ or } Y_x = \frac{Z_1 Y_2}{Z_3} \]  

(51.32)
Since the quantities are complex, Equation 51.32 involves the adjustment of two parameters: magnitude and phase:

\[
|Z_1| = \left| \frac{Z_1}{Z_3} \right|, \quad \phi_1 = \phi_1 - \phi_3 + \phi_2
\]  

or real and imaginary parts, respectively.

An important property of an impedance bridge is the sensitivity \( \varepsilon \):

\[
\varepsilon = \left| \frac{\partial V_4}{\partial Z_x} \right| = V \frac{Z_2}{(Z_2 + Z_x)^2}
\]  

or (independent of \( Z_1 \))

\[
\varepsilon = V \frac{Z_2^2}{Z_2 (Z_1 + Z_3)^2}
\]

in the vicinity of zero crossing when the bridge is balanced.

The precision of the measurement not only depends on the exact zero adjustment, which can be enhanced by choosing the elements and the voltage according to Equation 51.35 to obtain a high sensitivity, but also on the realization of \( Z_1 \)…\( Z_n \). Mostly, these are connections of resistors and capacitors. Inductors are avoided because they always have a resistive component and it is difficult and expensive to manufacture inductors with exactly defined and reproducible electrical properties. There exist various types of bridges depending on how the elements are designed and interconnected. To choose the correct configuration, it must be known whether the unknown impedance is capacitive or inductive; otherwise, a zero adjustment is not always possible since the balancing condition cannot be fulfilled. Bridges are therefore principally used to measure capacitances and inductances as well as loss and quality factors of capacitors and coils. Since magnitude and phase conditions must be matched simultaneously, two elements must be tuned. To obtain a wide measurement range, the variable elements are designed as combinations of switchable and tunable capacitors and resistors. The sensitivity of the zero indicator can
be changed for global search and final adjustment. Unfortunately, magnitude and phase cannot be adjusted independently of each other. If the balancing is performed by hand, a suitable strategy is to search the minimum voltage by tuning each element successively.

Frequently used bridges are the Wheatstone bridge (Figure 51.12) for the measurement of lossy capacitances, and the Hay bridge (Figure 51.13) to determine inductivity and quality factor of coils. Because of its symmetrical structure, the balancing condition for the Wheatstone bridge is simply:

**FIGURE 51.12** Wheatstone bridge for the capacitance and dissipation factor measurement of capacitors. The balancing condition is frequency independent. The resistor $R_1$ and the capacitor $C_1$ must be tuned successively until the bridge is balanced.

**FIGURE 51.13** Hay bridge for the measurement of the inductance and the quality factor of coils. If $Q$ is sufficiently high, the inductance can be determined nearly frequency independent.
which is independent of frequency.

The measurement of a coil with the Hay bridge requires that:

\[ R_x = \alpha R_1, \quad C_x = \alpha C_1, \quad \alpha = \frac{R_3}{R_2} \]  \hspace{2cm} (51.36)

from which the quality factor is obtained as:

\[ Q = \frac{\omega L_x}{R_x} = \frac{1}{\omega R_x C_x} \]  \hspace{2cm} (51.38)

The inductance of high-Q coils can be determined frequency independent since

\[ L_x = R_1 R_2 C_3 \quad \text{if} \quad \left(\frac{\omega R_x C_x}{1}\right)^2 \ll 1 \]  \hspace{2cm} (51.39)

A very interesting alternative is the Maxwell bridge (Figure 51.14), since it requires only resistors as variable elements, which can be manufactured with high precision. The balancing is frequency independent and leads to:

\[ R_x = \frac{R_1 R_2}{R_3}, \quad L_x = R_1 R_2 C_3, \quad Q = \omega CR_1 \]  \hspace{2cm} (51.40)
Nevertheless, the Hay bridge is preferred for high-Q coils, because a very large value of $R_i$ is required for the Maxwell bridge leading to a disadvantageous balancing [9].

**Resonant Method**

Using the coil as part of a resonance circuit as in Figure 51.15 and tuning $C$ to maximum voltage, the quality factor can be measured directly as:

$$Q = \frac{V_{C,\text{max}}}{V} = \frac{1}{\omega R_i C} \quad (51.41)$$

The unknown inductance is then obtained from the test frequency by means of the resonance condition:

$$L_x = \frac{1}{\omega^2 C} \quad (51.42)$$

If a capacitor with sufficiently low losses is used, $Q$ values as high as 1000 can be measured.

**Network Analysis Methods**

**Frequency Domain**

In the case of distributed elements, measurements of currents and voltages depend on the position and are often not directly applicable to high-frequency devices like waveguides or microstrip lines. For that reason the determination of immittances is derived from measuring the reflection coefficient. Equation 51.23 shows the importance of defining a proper measurement plane. This is the cross-section of the line or waveguide perpendicular to the direction of propagation at a definite length $l_0$, where the reflection coefficient has to be measured. It can then be transformed along the line toward load or source using this relation or the Smith chart. Exact microwave measurements are very sophisticated and need a lot of practical experience. Further details can be found in the literature [5, 10–12].

Automated and precise immittance measurements over a wide frequency range are best carried out with a vector network analyzer [11]. Unfortunately, this is also the most expensive method. The principle of measurement is shown in Figure 51.16. A power divider splits the incident signal into a transmitted and a reference part. The directional bridge or coupler separates forward and backward traveling waves, and the reflected signal now appears in the branch with the phase-sensitive voltmeter $V_c$. Using a bridge...
with impedances matched to the line \((Z_1 = Z_2 = Z_3 = Z_0)\), the voltage in the diagonal branch is given by (Figure 51.11):

\[
V_d = \frac{Z_x - Z_0}{2(Z_x + Z_0)} V = V_2
\]  

(51.43)

and thus the reflection coefficient:

\[
\Gamma = \frac{V_x}{V_1} = \alpha \frac{V_2}{V_1}
\]  

(51.44)

is directly proportional to the voltage ratio.

Network analyzers use an automatic error correction to eliminate the effect of internal and external couplers and junctions. Because of that, a calibration procedure with standard terminations is necessary. These terminations must be manufactured very precisely, since they define the measurement plane and determine the overall measurement error.

**Time Domain**

It is often necessary to locate an impedance step, whether to find out the distance of a cable defect or to track down the origin of reflections within a connection. To this end, high-performance vector network analyzers have a Fourier transform procedure. But there also exist cheaper time domain reflectometers (TDR) [13, 14]. They use an incident step or impulse signal (Figure 51.17) and the reflected signal is separated by means of a directional coupler and displayed on a CRT in the time domain. From the shape of the signal, the impedance step can be localized by means of the time delay:

\[
l = \frac{1}{2} v_g t
\]  

(51.45)

with \(v_g\) as signal or group velocity on the line varying from step to step. Characteristic and magnitude of the impedance can only be estimated, since phase information is usually not available. TDR measurements are restricted to the localization of impedance steps and not to be recommended for exact measurements. Moreover, additional pulse deformations occur in dispersive waveguides.
A broad range of instrumentation for measuring immittance is available. Some of these instruments are included in Table 51.1. Table 51.2 provides the names and addresses of some companies that produce immittance-measuring instrumentation.

Defining Terms

Admittance ($Y$): The reciprocal of impedance.

Immittance: A response function for which one variable is a voltage and the other a current. Immittance is a general term for both impedance and admittance, used where the distinction is irrelevant.

Impedance ($Z$): The ratio of the phasor equivalent of a steady-state sine-wave voltage to the phasor equivalent of a steady-state sine-wave current. The real part is the resistance, the imaginary part is the reactance.

Phasor: A complex number, associated with sinusoidally varying electrical quantities, such that the absolute value (modulus) of the complex number corresponds to either the peak amplitude or root-mean-square (rms) value of the quantity, and the phase (argument) to the phase angle at zero time. The term “phasor” can also be applied to impedance and related complex quantities that are not time dependent.

Reflection coefficient: At a given frequency, at a given point, and for a given mode of propagation, the ratio of voltage, current, or power of the reflected wave to the corresponding quantity of the incident wave.

Further Information

Q factor is a method of characterizing the rate of dissipation of energy from an oscillating system. Q is defined as $2\pi$ times the energy stored in a resonant system divided by the energy dissipated per cycle. The term system used in this context refers to any type of resonance: mechanical, electrical, nuclear, etc. For the purposes of this Handbook, Q will be that of an electric circuit. Also, for the discussion of Q, very low values of Q, typically less than 10, will not be considered as these low values of Q produce highly damped oscillations that are more exponential than oscillatory and the concept of Q does not fit.

A common interpretation of Q is quality factor that explains the use of the letter, Q, but this is misleading. A component that has a high Q is not always beneficial and may not be of high quality. In many circuits, a component requires a specific value of Q rather than “higher is better.” In other cases, a high Q is an advantage.

The Q factors encountered in common circuit components range from a low of about 50 for many inductors to nearly 1 million found in high-quality quartz crystals. Q can be applied to a resonant circuit or to capacitors and inductors. When Q is applied to a component, such as an inductor, the Q would be that obtained if the inductor were used in a resonant circuit with a capacitor that dissipates no energy. In this case, the value of Q depends on the frequency.

For most LC resonant circuits, the losses in the inductor dominate and the Q of the inductor is, essentially, the Q of the circuit. It is easy to make very low-loss capacitors even in the UHF region. On the other hand, varactor diodes have considerably more loss than fixed capacitors, and a varactor can play a more significant role in setting the circuit Q.

### 52.1 Basic Calculation of Q

Figure 52.1 shows a simple resonant circuit. The capacitor can store energy in the electric field and the inductor in the magnetic field. The circuit oscillates with the energy transferring between the two elements. For the ideal elements shown, this continues forever. Since the definition of Q has the energy lost per cycle in the denominator — which is zero — the result is an infinite Q.

In practice, circuit elements are not perfect and the energy initially contained within this circuit would be lost by the circuit and the oscillations would decrease in amplitude as the energy diminished. Energy loss in a circuit is represented by that in a resistor which can be included in one of two ways. The first
way is shown in Figure 52.2(a), where the resistor is in series with the capacitor and inductor. A second representation is a parallel resistor as shown in Figure 52.2(b).

To derive the relationship between the circuit element values and the $Q$ of the circuit, either the current or voltage of the circuit can be used in the equations. Current is the obvious choice for a series circuit, while voltage is the common thread for the parallel circuit. Assume that the amplitude of the current through the series circuit of Figure 52.2(a) is given by:

$$i(t) = I(0) \cos(2\pi f_0 t) \tag{52.1}$$

where $f_0 = \text{Resonant frequency} = \frac{1}{2\pi \sqrt{LC}} \tag{52.2}$

and $I(t)$ is the amplitude, which is decreasing in some unspecified fashion. The circuit's peak current occurs when the cosine function is equal to 1 and all of the energy is contained in the inductor and is equal to $(1/2)LI_0^2$.

Assume that a relatively high $Q$ is present in this circuit and that $I(t)$ changes by only a slight amount during the time of one cycle. During this cycle, the peak current is $I(t)$, and the rms value of the current is $(0.707)I(t)$. Therefore, the energy dissipated in one cycle is $(0.5)I^2(t)Rf_0$. Substituting these values in the definition of $Q$ yields:

$$Q = \frac{1}{2} \frac{I_0^2(t)}{r} = \frac{2\pi f_0 L}{r} = \frac{X_L}{4\pi f_0} \tag{52.3}$$

where $X_L$ is the reactance of the inductor. The same procedure can be used with the parallel resonant circuit of Figure 52.2(b) using voltage equations to obtain the relationship between a parallel resistance and $Q$, which is:

$$Q = \frac{R}{X_L} \tag{52.4}$$

It is very important to understand the nature of the circuit resistance in Figure 52.2(a) and (b). This resistance represents all of the losses in the resonant circuit. These losses are from a variety of sources,
such as the resistance of the wire to make an inductor or the leakage current of a capacitor. It can also represent the deliberate addition of resistors to set the $Q$ of the circuit to a specific value. The resistance shown in the circuits of Figure 52.2 represents the equivalent resistance of all of the energy losses. This resistance cannot be measured with an ohmmeter as the value of the equivalent resistor is a function of frequency and other variables such as signal level. Some of the loss in a resonant circuit is due to radiation, which is a function of frequency. The resistance of conductors is mostly due to skin effect, which increases with increasing frequency. The losses in the ferromagnetic materials used for making some inductors are nonlinear; thus, the equivalent resistance is not only a function of frequency but of signal level.

Most resonant circuits are not stand-alone circuits as shown in Figure 52.2, but are a part of other circuits where there are sources and loads. These additional resistances further remove energy from the resonant circuit. The $Q$ of a resonant circuit when there are sources and loads is called the loaded $Q$. In most applications of resonant circuits, the $Q$ of the resonance is set by the external loads rather than the capacitor and inductor that form the resonance.

### 52.2 Bandwidth and $Q$

The **bandwidth** of a resonant circuit is a measure of how well a resonant circuit responds to driving signals of a frequency near the resonant frequency and is a function of $Q$. The relationship between the 3 dB bandwidth and $Q$ will be derived.

Applying a driving signal to a resonant circuit can overcome the losses of the circuit and cause the resonant circuit to oscillate indefinitely. As an example of this, consider the voltage generator in the series resonant circuit shown in Figure 52.3.

When the frequency of the voltage source is equal to the resonant frequency of the circuit, the equivalent impedance of the series resonant circuit is the resistance of the circuit and the current in the circuit, simply $E/r$.

At frequencies higher or lower than the resonant frequency, the impedance of the circuit is greater because the net reactance is not zero and the circuit current will be less than at resonance.

At what frequency will the circuit current be 3 dB less than at resonance? This frequency is where the circuit impedance is 1.414 that of the impedance at resonance. This is the frequency where the reactive part of the impedance is equal to the real part. This situation occurs at two frequencies. Below the resonant frequency, the net reactance is capacitive and is equal to $r$, while at a second frequency above the resonant frequency, the reactance is inductive and equal to $r$. This can be represented by two equations for the two frequencies:

For $f_i > f_0$,

$$\left| X_L - X_C \right| = 2\pi f_i L - \frac{1}{2\pi f_i C} = \left( \frac{f_i}{f_0} \right)^2 - 1 = r$$

$$\left( \frac{f_i}{f_0} \right)^2 - 1 = 0$$

$$\left( \frac{f_i}{f_0} \right) = \frac{1}{Q} \pm \frac{1}{\sqrt{4Q^2} + 1}$$

**FIGURE 52.3** A series resonant circuit showing a driving source.
For $f_2 < f_0$,

$$X_L - X_C = \frac{1}{2\pi f_0 C} - 2\pi f_2 L = \left(\frac{f_2}{f_0}\right)^2 - 1 = r \quad (52.6)$$

$$\left(\frac{f_2}{f_0}\right)^2 + 1 + \left(\frac{f_2}{f_0}\right) = 1 = 0$$

$$\left(\frac{f_2}{f_0}\right) = \frac{1}{2Q} \pm \frac{1}{4Q^2} + 1$$

$$f_2 - f_1 = \frac{f_0}{Q} = \text{bandwidth}$$

**Measuring Q**

There are a number of methods of measuring Q using a variety of bridges, several of which are described in [1]. One method of measuring a capacitive or inductive Q is to place the component in a resonant circuit. When the Q to be measured of a device that is, in itself, a resonant circuit such as quartz crystal, similar techniques are used except the device’s own resonance is used for the measurement. Circuit voltages or currents are measured at the resonance frequency and the Q is determined.

### 52.3 The Q-Meter

One simple and very popular method of measuring Q is with a device called, appropriately, the Q-meter. Consider the resonant circuit in Figure 52.4 for measuring the Q of inductors. This circuit has a very low-loss capacitor of known value and a constant voltage source.

The usual components measured by the Q-meter are inductors. It was previously mentioned that inductors are the weak link in resonant circuits, and the Q of a circuit is usually set by the inductor. The Q-meter can measure capacitance and capacitor Q. In this theoretical circuit, the circuit resistance is the equivalent series resistance of the inductor under test. This is due to the fact the variable capacitor is assumed to be lossless, the generator has zero resistance, and the voltmeter does not appreciably load the circuit. In a real circuit, it is not possible to achieve this situation, but the instrument is designed to approach this goal.

To measure the Q of an inductor using the Q-meter, the generator is set to the desired frequency while the variable capacitor tunes the circuit to resonance as indicated by the peak reading of the voltmeter.

At resonance, the impedance of the circuit is simply the equivalent series resistance of the inductor. This sets the current of the circuit as:

$$I = \frac{E}{R_X} \quad (52.7)$$

where $E$ is the generator voltage and $R_X$ is the equivalent resistance of the inductor.

Because the circuit is at resonance, the voltages of the two reactances are equal and of opposite phase. Those voltages are:

$$V = IX_C \quad \text{or} \quad V = IX_L \quad (52.8)$$

where $X_C$ is the capacitive reactance and $X_L$ is the inductive reactance, which are numerically equal at resonance.

Substituting the relationship of the circuit current, the result is:

$$V = \frac{EX_L}{R_X} = \frac{EX_C}{R_X} = EQ \quad (52.9)$$
Therefore, the voltage across the reactances is equal to \( Q \) times the applied voltage. If, as an example, the voltage source were 1 V, the voltmeter would read \( Q \) directly. \( Q \) values of several hundred are common and, therefore, voltages of several hundred volts could be measured. Modern circuits do not typically encounter voltages of this magnitude, and many components cannot withstand this potential. Therefore, most \( Q \)-meters use a much smaller source voltage, typically 20 mV.

If the frequency of the source and the circuit capacitance are known, it is possible to calculate the inductance of the unknown.

## 52.4 Other \( Q \) Measuring Techniques

There are very few \( Q \)-meters being manufactured today, although there are thousands of old \( Q \)-meters still in use. Because the \( Q \)-meter was the only accepted method of measuring \( Q \) for so many years, it will take decades before alternative methodologies overtake the \( Q \)-meter.

Measuring \( Q \) without a \( Q \)-meter involves a variety of \( RLC \) measuring instruments that measure the vector impedance and calculate \( Q \). The calculated \( Q \) value is not as valid as that determined with a \( Q \)-meter unless the \( RLC \) meter is capable of measuring \( Q \) at the desired frequency. Only the more sophisticated, and expensive, \( RLC \) meters allow the use of any test frequency. Despite the new sophisticated \( RLC \) measuring instruments, there is an adapter for one model \( RLC \) instrument that allows the classic \( Q \)-meter-style measurement to be made.

Because vector impedance measurement is covered elsewhere in this Handbook, the remainder of this section will be devoted to measurements using the \( Q \)-meter.

## 52.5 Measuring Parameters Other than \( Q \)

In addition to \( Q \), the \( Q \)-meter can be used to measure inductance, the \( Q \) or dissipation factor of a capacitor, and the distributed capacitance, \( C_d \), of an inductor.

If an inductor with capacitance \( C_d \) is placed in the \( Q \)-meter circuit, the total circuit capacitance includes both the \( Q \)-meter’s capacitance plus the additional \( C_d \). Therefore, when resonance is achieved, the actual resonating capacitance is more than what is indicated on the \( Q \)-meter capacitor’s dial. If \( C_d \) is not included in the calculation of inductance, the resulting value would be too large.

In many applications, the actual inductance is not the important parameter to be measured by the \( Q \)-meter. The actual parameter being determined is “what capacitance is required to resonate the particular inductor at a specific frequency,” regardless of \( C_d \).

In other applications, such as inductors that are to be used in wide-range oscillators, where \( C_d \) will limit the tuning range, \( C_d \) is an important parameter.

The \( Q \)-meter can be used to determine \( C_d \), which will also allow for an accurate calculation of inductance. Determining \( C_d \) is a matter of resonating the inductor under test at more than one frequency.

To understand how the two-frequency measurement will allow the determination of \( C_d \), assume an inductor is resonated at a frequency \( f_1 \). The relationship between the applied frequency, \( f_1 \), and the capacitor of the \( Q \)-meter to obtain resonance is:
where $C_1$ is the capacitance set on the $Q$-meter.

Resonating the same inductor at a second, higher, frequency, $f_2$, requires a $Q$-meter capacitance of $C_2$ such that:

$$f_2 = \frac{1}{2\pi\sqrt{L(C_1 + C_d)}} \quad (52.11)$$

This implies that $C_2$ is a smaller capacitance than $C_1$. Using these two equations and solving for $C_d$, the following result is obtained.

$$C_d = \frac{C_2f_1^2 - C_1f_2^2}{f_1^2 - f_2^2} \quad (52.12)$$

A convenient relationship between $f_1$ and $f_2$ is to set $f_2 = 1.414 f_1$. With frequencies thus related, the distributed capacitance is:

$$C_d = C_1 - 2C_2 \quad (52.13)$$

$C_d$ causes errors in the measurement of $Q$ because of current through the $C_d$. The $Q$ measured by the $Q$-meter is called the “effective $Q$.” Since large inductors with significant $C_d$ are no longer in common use because of the use of active filters, the distinction between effective $Q$ and real $Q$ is seldom considered. For additional information about effective $Q$ and distributed capacitance, see [2].

To measure capacitors on the $Q$-meter, a relatively high $Q$ inductor is connected to the inductance terminals on the $Q$-meter and resonated. The capacitor to be measured is connected to the capacitor terminals, which increases the circuit capacitance. The $Q$-meter variable capacitor is adjusted to regain resonance, which requires that the capacitance be reduced by an amount equal to the unknown capacitor.

The $Q$ of the capacitor can be measured. The addition of the capacitor reduces the circuit $Q$ because of the additional loss introduced by the capacitor. In the description of the $Q$-meter, the $Q$-meter’s variable capacitor is assumed to have no loss.

Measuring the $Q$ of a capacitor using the $Q$-meter is seldom done. This is because most capacitors have very high $Q$ values. There are special cases, such as measuring the $Q$ of a transducer or a varactor diode, where low $Q$ values are encountered.

The unknown capacitor is connected to the CAP terminals of the $Q$-meter, which are simply in parallel with the $Q$-meter’s variable capacitor. The variable capacitor in the $Q$-meter is set to the minimum capacitance and a suitable inductor is placed across the IND (inductor) terminals. The $Q$-meter is resonated using the frequency control rather than the variable capacitance.

For best results, the $Q$ of the inductor must be considerably greater than that of the unknown capacitor, and the unknown capacitance must be considerably greater than the internal capacitance. If these criteria are met, the $Q$ of the unknown capacitor can be read from the $Q$-meter. If these criteria are compromised, corrections can be made but the equations become complex and the accuracy degrades.

Most $Q$-meters provide measurement ranges to about 500 or to 1000. This is sufficient for measuring inductors, which was the main purpose of the $Q$-meter. For measuring high-$Q$ devices such as ceramic resonators with $Q$ values greater than 1000 or for quartz resonators with $Q$ values extending into the hundreds of thousands, the $Q$-meter technique is insufficient. A high-$Q$ circuit implies very little energy loss, and the energy that must be removed to make a measurement must be very small if $Q$ is to be measured accurately.
Defining Terms

**Bandwidth:** A measurement of the amount of frequency spectrum occupied by a signal or the equivalent spectrum covered by a circuit that passes a finite band of frequencies. There are a number of methods of defining bandwidth, depending on the nature of the spectrum. Relative to resonant circuits, the bandwidth is measured between the –3 dB points of the passband.

**Distributed capacitance:** The amount of capacitance added to an inductor typically from the capacitance due to adjacent wires in a solenoid-type inductor. The distributed capacitance is given as a single capacitance figure for a specific inductor and can be defined as the equivalent capacitance across the entire coil. This would also allow the inductor to have a self-resonant frequency where the inductor resonates with the distributed capacitance with no external capacitance.

**Effective inductance:** Due to distributed capacitance, less capacitance than that calculated from an inductance value is required to resonate a circuit. If the actual capacitance required to resonate a circuit is used to calculate an inductance value, the resulting inductance value will be higher than the theoretical inductance value. This higher value is called the “effective inductance.” The actual inductor cannot be considered as a pure inductance of a value equal to the effective inductance because the real inductor has a resonant frequency that a pure inductance does not.

**Q:** A measurement of the rate of energy loss in a resonant circuit.

**Q-Meter:** An instrument for measuring Q factor by resonating the circuit and measuring the voltage across the reactances.

References

A sine-wave signal will have only a single-frequency component in its spectrum; that is, the frequency of the tone. However, if the sine wave is transmitted through a system (such as an amplifier) having some nonlinearity, then the signal emerging from the output of the system will no longer be a pure sine wave. That is, the output signal will be a distorted representation of the input signal. Since only a pure sine wave can have a single component in its frequency spectrum, this situation implies that the output must have other frequencies in its spectral composition. In the case of harmonic distortion, the frequency spectrum of the distorted signal will consist of the fundamental (which is the same frequency as the input sine wave) plus harmonic frequency components that are at integer multiples of the fundamental frequency. Taken together, these will form a Fourier representation of the distorted output signal. This phenomenon can be described mathematically. Refer to Figure 53.1, which depicts a sine-wave input signal $x(t)$ at frequency $f_1$ applied to the input of a system $A(x)$, which has an output $y(t)$. Assume that system $A(x)$ has some nonlinearity. If the nonlinearity is severe enough, then the output $y(t)$ might have excessive harmonic distortion such that its shape no longer resembles the input sine wave. Consider the example where the system $A(x)$ is an audio amplifier and $x(t)$ is a voice signal. Severe distortion can result in a situation where the output signal $y(t)$ does not represent intelligible speech. The total harmonic distortion (THD) is a figure of merit that is indicative of the quality with which the system $A(x)$ can reproduce an input signal $x(t)$. The output signal $y(t)$ can be expressed as:

$$y(t) = a_0 + \sum_{k=1}^{N} a_k \cos(2\pi k f_1 t + \theta_k)$$  \hspace{1cm} (53.1)$$

where the $a_k$, $k = 0, 1, \ldots, N$ are the magnitudes of the Fourier coefficients, and $\theta_k$, $k = 0, 1, \ldots, N$ are the corresponding phases. The THD is defined as the percentage ratio of the rms voltage of all harmonics components above the fundamental frequency to the rms voltage of the fundamental. Mathematically, the definition is written:

$$\text{THD} = \frac{\sqrt{\sum_{k=2}^{N} a_k^2}}{a_1} \times 100\%$$  \hspace{1cm} (53.2)$$
If the system has good linearity (which implies low distortion), then the THD will be a smaller number than that for a system having poorer linearity (higher distortion). To provide the reader with some feeling for the order of magnitude of a realistic THD, a reasonable audio amplifier for an intercom system might have a THD of about 2% or less, while a high-quality sound system might have a THD of 0.01% or less. For the THD to be meaningful, the bandwidth of the system must be such that the fundamental and the harmonics will lie within the passband. Therefore, the THD is usually used in relation to low-pass systems, or bandpass systems with a wide bandwidth. For example, an audio amplifier might have a 20 Hz to 20 kHz bandwidth, which means that a 1-kHz input sine wave could give rise to distortion up to the 20th harmonic (i.e., 20 kHz), which can lie within the passband of the amplifier. On the other hand, a sine wave applied to the input of a narrow-band system such as a radio frequency amplifier will give rise to harmonic frequencies that are outside the bandwidth of the amplifier. These kinds of narrow-band systems are best measured using intermodulation distortion, which is treated elsewhere in this Handbook.

For the rest of the discussion at hand, consider the example system illustrated in Figure 53.1 which shows an amplifier system \( A(x) \) that is intended to be linear but has some undesired nonlinearities. Obviously, if a linear amplifier is the design objective, then the THD should be minimized.

### 53.1 Mathematical Background

Let \( y = A(x) \) represent the input-output transfer characteristic of the system \( A(x) \) in Figure 53.1 containing the nonlinearity. Expanding into a power series yields

\[
A(x) = \sum_{i=0}^{\infty} c_i x^i = c_0 + c_1 x + c_2 x^2 + c_3 x^3 + \ldots
\]  

(53.3)

Let the input to the system be \( x = \cos(2\pi f_0 t) \). Then the output will be

\[
y = A(x) = c_0 + c_1 A_0 \cos(2\pi f_0 t) + c_2 A_0^2 \cos^2(2\pi f_0 t) + c_3 A_0^3 \cos^3(2\pi f_0 t) + \ldots
\]  

(53.4)

This can be simplified using the trigonometric relationships:

\[
\cos^2(\theta) = \frac{1}{2} - \frac{1}{2} \cos(2\theta)
\]  

(53.5)

\[
\cos^3(\theta) = \frac{3}{4} \cos(\theta) + \frac{1}{4} \cos(3\theta)
\]  

(53.6)
and so on. Performing the appropriate substitutions and collecting terms results in an expression for the distorted signal \( y(t) \) that is of the form shown in Equation 53.1. The THD can then be computed from Equation 53.2.

Closer inspection of Equations 53.6 and 53.8 reveal that a cosine wave raised to an odd power gives rise to only the fundamental and odd harmonics, with the highest harmonic corresponding to the highest power. A similar phenomenon is observed for a cosine raised to even powers; however, the result is only a dc component and even harmonics without any fundamental component. In fact, any nonlinear system that possesses an odd input-output transfer characteristic \( A(x) \) (i.e., the function \( A(x) \) is such that \( -A(x) = A(-x) \)) will give rise to odd harmonics only. Consider Figure 53.2, which illustrates an example of two-sided symmetrical clipping. It is an odd function. The application of a sine wave to its input will result in a waveform similar to that shown in Figure 53.3, which has only odd harmonics as shown in Figure 53.4. The majority of physical systems are neither odd nor even. (An even function is one that has the property \( A(x) = A(-x) \); for example, a full-wave rectifier.) Consider the enhancement NMOS transistor illustrated in Figure 53.5, which has the square-law characteristic shown. Assume that the voltage \( V_{GS} \) consists of a dc bias plus a sine wave such that \( V_{GS} \) is always more positive than \( V_T \) (the threshold voltage). Then the current flowing in the drain of this NMOS transistor could have the appearance shown in Figure 53.6. It is observed that the drain current is distorted, since the positive-going side has a greater swing than the negative-going side. The equation for the drain current can be derived mathematically as follows. A MOS transistor operating in its saturation region can be approximated as a square-law device:

\[
\begin{align*}
\cos^3(\theta) & = \frac{1}{8} - \frac{1}{2}\cos(2\theta) + \frac{1}{8}\cos(4\theta) \\
\cos^5(\theta) & = \frac{5}{8}\cos(\theta) + \frac{5}{16}\cos(3\theta) + \frac{1}{16}\cos(5\theta)
\end{align*}
\] (53.7) (53.8)

and so on. Performing the appropriate substitutions and collecting terms results in an expression for the distorted signal \( y(t) \) that is of the form shown in Equation 53.1. The THD can then be computed from Equation 53.2.

Closer inspection of Equations 53.6 and 53.8 reveal that a cosine wave raised to an odd power gives rise to only the fundamental and odd harmonics, with the highest harmonic corresponding to the highest power. A similar phenomenon is observed for a cosine raised to even powers; however, the result is only a dc component and even harmonics without any fundamental component. In fact, any nonlinear system that possesses an odd input-output transfer characteristic \( A(x) \) (i.e., the function \( A(x) \) is such that \( -A(x) = A(-x) \)) will give rise to odd harmonics only. Consider Figure 53.2, which illustrates an example of two-sided symmetrical clipping. It is an odd function. The application of a sine wave to its input will result in a waveform similar to that shown in Figure 53.3, which has only odd harmonics as shown in Figure 53.4. The majority of physical systems are neither odd nor even. (An even function is one that has the property \( A(x) = A(-x) \); for example, a full-wave rectifier.) Consider the enhancement NMOS transistor illustrated in Figure 53.5, which has the square-law characteristic shown. Assume that the voltage \( V_{GS} \) consists of a dc bias plus a sine wave such that \( V_{GS} \) is always more positive than \( V_T \) (the threshold voltage). Then the current flowing in the drain of this NMOS transistor could have the appearance shown in Figure 53.6. It is observed that the drain current is distorted, since the positive-going side has a greater swing than the negative-going side. The equation for the drain current can be derived mathematically as follows. A MOS transistor operating in its saturation region can be approximated as a square-law device:

\[
I_{DS} = \frac{\mu C_{GS}}{2} \frac{W}{L} (V_{GS} - V_T)^2
\] (53.9)
If the gate of the $n$-channel enhancement MOSFET is driven by a voltage source consisting of a sine-wave generator in series with a dc bias, i.e.:

$$V_{GS} = V_b + A_s \sin\left(2\pi f_o t\right)$$  \hspace{1cm} (53.10)

then the current in the drain can be written as:

$$I_{DS} = \frac{hC_{ox} W}{2 L} \left[V_b + A_s \sin\left(2\pi f_o t\right) - V_T\right]^2$$  \hspace{1cm} (53.11)
Expanding and using the trigonometric relationship:

\[
\sin^2(\theta) = \frac{1}{2} - \frac{1}{2} \sin \left( 2\theta + \frac{\pi}{2} \right) \tag{53.12}
\]

Equation 53.11 can be rewritten as:

\[
I_{DS} = \frac{\mu C_{ox}}{2} W \left[ \left(V_B - V_T\right)^2 + \frac{A_2}{2} + 2 \left(V_B - V_T\right) A_3 \sin \left(2\pi f_0 t\right) - \frac{A_2^2}{2} \sin \left(4\pi f_0 t\right) + \frac{\pi}{2} \right] \tag{53.13}
\]

which clearly shows the dc bias, the fundamental, and the second harmonic that are visible in the spectrum of the drain current \(I_{DS}\) in Figure 53.7. There is one odd harmonic (i.e., the fundamental) and two even harmonics (strictly counting the dc component and the second harmonic). This particular transfer characteristic is neither odd nor even. Finally, for an ideal square-law characteristic, the second harmonic

\[
\theta = \frac{2 \pi}{\lambda} \tag{53.5}
\]

\[
\sin \theta = \frac{2 V}{V_i} \tag{53.6}
\]

\[
I_{DS} = K \left(V_{gs} - V_T\right)^2 \tag{53.7}
\]
is the highest frequency component generated in response to a sine-wave input. Another example of a transfer characteristic that is neither even nor odd is single-sided clipping as shown in Figure 53.8, which gives rise to the distortion of Figure 53.9. One last example of an odd input-output transfer characteristic is symmetrical cross-over distortion as depicted in Figure 53.10. The distorted output in response to a 1-kHz sine-wave input is shown in Figure 53.11. The spectrum of the output signal is shown in Figure 53.12. Note that only odd harmonics have been generated.

To round out the discussion, consider a mathematical example wherein the harmonics are derived algebraically. Consider an input-output transfer function $f(x) = c_1x + c_3x^3 + c_5x^5$ that has only odd powers of $x$. If the input is a cosine $x = A_0 \cos(2\pi f_0 t)$, then the output will be of the form:

---

FIGURE 53.7 The drain current contains a dc bias, the fundamental, and the second harmonic only, for an ideal device.

FIGURE 53.8 Single-sided clipping is neither even nor odd.
This can be simplified using the trigonometric relationships given in Equations 53.5 through 53.8 with the following result:

\[
y(t) = f(x) = c_1A_0 \cos(2\pi f_0 t) + c_3A_0^3 \cos^3(2\pi f_0 t) + c_5A_0^5 \cos^5(2\pi f_0 t) \quad (53.14)
\]

\[
y(t) = \left( c_1A_0 + \frac{3c_1A_0^3}{4} + \frac{5c_3A_0^5}{8} \right) \cos(2\pi f_0 t) + \left( \frac{c_1A_0^3}{4} + \frac{5c_3A_0^5}{16} \right) \cos(2\pi 3f_0 t) + c_5A_0^5 \cos^5(2\pi 5f_0 t) \quad (53.15)
\]
Clearly, only the fundamental plus the third and fifth harmonics are present. Should the exercise be repeated for an input-output transfer function consisting of only even powers of $x$, then only a dc offset plus even harmonics (not the fundamental) would be present in the output.

53.2 Intercept Points (IP)

It is often desirable to visualize how the various harmonics increase or decrease as the amplitude of the input sine wave $x(t)$ is changed. Consider the example of a signal applied to a nonlinear system $A(x)$ having single-sided clipping distortion as shown in Figure 53.8. The clipping becomes more severe as the amplitude of the input signal $x(t)$ increases in amplitude, so the distortion of the output signal $y(t)$
becomes worse. The intercept point (IP) is used to provide a figure of merit to quantify this phenomenon. Consider Figure 53.13, which shows an example of the power levels of the first three harmonics of the distorted output \( y(t) \) of a hypothetical system \( A(x) \) in response to a sine-wave input \( x(t) \). It is convenient to plot both axes on a log scale. It can be seen that the power in the harmonics increases more quickly than the power in the fundamental. This is consistent with the observation of how clipping becomes worse as the amplitude increases. It is also consistent with the observation that, in the equations above, the higher harmonics will rapidly become more prominent because they are proportional to higher exponential powers of the input signal amplitude. The intercept point for a particular harmonic is the power level where the extrapolated line for that harmonic intersects with the extrapolated line for the fundamental. The second-order intercept is often abbreviated IP2, the third-order intercept abbreviated IP3, etc.

53.3 Measurement of the THD

Classical Method
The traditional method of measuring THD is shown in Figure 53.14. A sine-wave test stimulus \( x(t) \) is applied to the input of the system \( A(x) \) under test. The system output \( y(t) \) is fed through a bandpass

![FIGURE 53.13](image1.png) An example showing the second- and third-order intercept points for a hypothetical system. Both axes are plotted on a logarithmic scale.

![FIGURE 53.14](image2.png) Illustrating the classical method of measuring THD.
filter tuned to the frequency of the input stimulus to extract the signal. Its power $p_1$ can be measured with a power meter. The bandpass filter is then tuned to each of the desired harmonics in turn and the measurement is repeated to determine the required $p_i$. The THD is then calculated from:

$$\text{THD} = \frac{\sum_{k=2}^{N} P_k}{P_1} \times 100\% \quad (53.16)$$

In the case of an ordinary audio amplifier, nearly all of the power in the distorted output signal is contained in the first 10 or 11 harmonics. However, in more specialized applications, a much larger number of harmonics might need to be considered.

**Spectrum Analyzer Method**

THD measurements are often made with a spectrum analyzer using the setup shown in Figure 53.15. The readings for the power levels of each of the desired harmonic components in the frequency spectrum of the distorted signal $y(t)$ are collected from the spectrum analyzer, usually in units of dB. They are converted to linear units by means of the relationship:

$$a_i = 10^{r_i/20} \quad (53.17)$$

where $r_i$ is the reading for the $i$th component in dB. The THD is then computed from Equation 53.2. The spectrum analyzer method can be considered as an extension of the classical method described above, except that the spectrum analyzer itself is replacing both the bandpass filter and the power meter.

**DSP Method**

*Digital signal processing* (DSP) techniques have recently become popular for use in THD measurement. In this method, the distorted output $y(t)$ is digitized by a precision A/D converter and the samples are stored in the computer’s memory as shown in Figure 53.16. One assumes that the samples have been collected with a uniform sample period $T_s$ and that appropriate precautions have been taken with regard to the Nyquist criterion and aliasing. Let $y(n)$ refer to the $n^{th}$ stored sample. A fast Fourier transform (FFT) is executed on the stored data using the relationship:

$$Y(k) = \sum_{n=0}^{N-1} y(n) e^{-j\frac{2\pi}{N}kn} \quad (53.18)$$
where \( N \) is the number of samples that have been captured. The frequency of the input test stimulus is chosen such that the sampling is coherent. Coherency in this context means that if \( N \) samples have been captured, then the input test stimulus is made to be a harmonic of the primitive frequency \( f_P \), which is defined as:

\[
f_P = \frac{f_s}{N} = \frac{1}{T_s N}
\]  

(53.19)

One can view the primitive frequency \( f_P \) as the frequency of a sinusoidal signal whose period is exactly equal to the time interval formed by the \( N \)-points. Thus, the frequency of the test stimulus can be written as:

\[
f_0 = M \times f_P = M \times \frac{f_s}{N} = \frac{M}{N} \times f_s
\]  

(53.20)

where \( M \) and \( N \) are integers. To maximize the information content collected by a set of \( N \)-points, \( M \) and \( N \) are selected so that they have no common factors, i.e., relatively prime. This ensures that every sample is taken at a different point on the periodic waveform. An example is provided in Figure 53.17, where \( M = 3 \) and \( N = 32 \). The FFT is executed on the distorted signal as per Equation 53.18, and then the THD is computed from:

\[
\text{THD} = \frac{\sum_{k=2}^{N} |Y(k \times M)|^2}{|Y(M)|^2} \times 100\%
\]  

(53.21)

53.4 Conclusions

The total harmonic distortion (THD) is a figure of merit for the quality of the transmission of a signal through a system having some nonlinearity. Its causes and some methods of measuring it have been discussed. Some simple mathematical examples have been presented. However, in real-world systems, it is generally quite difficult to extract all of the parameters \( c_k \) in the transfer characteristic. The examples were intended merely to assist the reader’s understanding of the relationship between even and odd functions and the harmonics that arise in response to them.
Defining Terms

**Total harmonic distortion (THD):** A numerical figure of merit of the quality of transmission of a signal, defined as the ratio of the power in all the harmonics to the power in the fundamental.

**Fundamental:** The lowest frequency component of a signal other than zero frequency.

**Harmonic:** Any frequency component of a signal that is an integer multiple of the fundamental frequency.

**Distortion:** The effect of corrupting a signal with undesired frequency components.

**Nonlinearity:** The deviation from the ideal of the transfer function, resulting in such effects as clipping or saturation of the signal.

Further Information

This chapter describes the principal sources of electric noise and discusses methods for the measurement of noise. The notations for voltages and currents correspond to the following conventions: dc quantities are indicated by an upper-case letter with upper-case subscripts, e.g., $V_{BE}$. Instantaneous small-signal ac quantities are indicated by a lower-case letter with lower-case subscripts, e.g., $v_n$. The mean-square value of a variable is denoted by a bar over the square of the variable, e.g., $v_n^2$, where the bar indicates an arithmetic average of an ensemble of functions. The root-mean-square or rms value is the square root of the mean-square value. Phasors are indicated by an upper-case letter and lower case subscripts, e.g.,
V_n. Circuit symbols for independent sources are circular, symbols for controlled sources are diamond shaped, and symbols for noise sources are square. In the evaluation of noise equations, Boltzmann’s constant is $k = 1.38 \times 10^{-23} \text{J K}^{-1}$ and the electronic charge is $q = 1.60 \times 10^{-19} \text{C}$. The standard temperature is denoted by $T_0$ and is taken to be $T_0 = 290 \text{K}$. For this value, $4kT_0 = 1.60 \times 10^{-20} \text{J}$ and the thermal voltage is $V_T = kT_0/q = 0.025 \text{V}$.

### 54.1 Thermal Noise

Thermal noise or Johnson noise is generated by the random collision of charge carriers with a lattice under conditions of thermal equilibrium [1–7]. Thermal noise in a resistor can be modeled by a series voltage source or a parallel current source having the mean-square values

\[ \overline{v_i^2} = 4kTR\Delta f \]  
\[ \overline{i_i^2} = \frac{4kT\Delta f}{R} \]

where $R$ is the resistance and $\Delta f$ is the bandwidth in hertz (Hz) over which the noise is measured. The equation for $\overline{v_i^2}$ is commonly referred to as the Nyquist formula. Thermal noise in resistors is independent of the resistor composition.

The crest factor for thermal noise is the ratio of the peak value to the rms value. A common definition for the peak value is the level that is exceeded 0.01% of the time. The amplitude distribution of thermal noise is modeled by a gaussian or normal probability density function. The probability that the instantaneous value exceeds 4 times the rms value is approximately 0.01%. Thus, the crest factor is approximately 4.

### 54.2 Spectral Density

The spectral density of a noise signal is defined as the mean-square value per unit bandwidth. For the thermal noise generated by a resistor, the voltage and current spectral densities, respectively, are given by:

\[ S_v(f) = 4kTR \]  
\[ S_i(f) = \frac{4kT}{R} \]

Because these are independent of frequency, thermal noise is said to have a uniform or flat distribution. Such noise is also called white noise. It is called this by analogy to white light, which also has a flat spectral density in the optical band.

### 54.3 Fluctuation Dissipation Theorem

Consider any system in thermal equilibrium with its surroundings. If there is a mechanism for energy in a particular mode to leak out of that mode to the surroundings in the form of heat, then energy can leak back into that mode from the surrounding heat by the same mechanism. The fluctuation dissipation theorem of quantum mechanics states that the average energy flow in each direction is the same. Otherwise, the system would not be in equilibrium.
Mathematically, the fluctuation dissipation theorem states, in general, that the generalized mean-square force $\overline{N^2}$ acting on a system in the frequency band from $f_1$ to $f_2$ is given by:

$$\overline{N^2} = 4kT \int_{f_1}^{f_2} \text{Re} \left[ Z(f) \right] df$$  \hspace{1cm} (54.5)

where $\text{Re} \left[ Z(f) \right]$ is the real part of the system impedance $Z(f)$ and $f$ is the frequency in hertz (Hz). For a mechanical system, the generalized force is the mechanical force on the system and the impedance is force divided by velocity. For an electric system, the generalized force is the voltage and the impedance is the ratio of voltage to current.

Equation 54.1 is a statement of the fluctuation dissipation theorem for a resistor. The theorem can be used to calculate the mean-square thermal noise voltage generated by any two-terminal network containing resistors, capacitors, and inductors. Let $Z(f)$ be the complex impedance of the network. The mean-square open-circuit thermal noise voltage is given by:

$$\overline{v_i^2} = 4kT \int_{f_1}^{f_2} \text{Re} \left[ Z(f) \right] df \approx 4kT \text{Re} \left[ Z(f) \right] \Delta f$$  \hspace{1cm} (54.6)

where $\Delta f = f_2 - f_1$ and the approximation holds if $\text{Re} \left[ Z(f) \right]$ is approximately constant over the band.

### 54.4 Equivalent Noise Resistance and Conductance

A mean-square noise voltage can be represented in terms of an equivalent noise resistance [8]. Let $\overline{v_i^2}$ be the mean-square noise voltage in the band $\Delta f$. The noise resistance $R_n$ is defined as the value of a resistor at the standard temperature $T_0 = 290$ K that generates the same noise. It is given by:

$$R_n = \frac{\overline{v_i^2}}{4kT_0 \Delta f}$$  \hspace{1cm} (54.7)

A mean-square noise current can be represented in terms of an equivalent noise conductance. Let $\overline{i_i^2}$ be the mean-square noise current in the band $\Delta f$. The noise conductance $G_n$ is defined as the value of a conductance at the standard temperature that generates the same noise. It is given by:

$$G_n = \frac{\overline{i_i^2}}{4kT_0 \Delta f}$$  \hspace{1cm} (54.8)

### 54.5 Shot Noise

Shot noise is caused by the random emission of electrons and by the random passage of charge carriers across potential barriers [1–7]. The shot noise generated in a device is modeled by a parallel noise current source. The mean-square shot noise current in the frequency band $\Delta f$ is given by:

$$\overline{i_{sh}^2} = 2qI \Delta f$$  \hspace{1cm} (54.9)

where $I$ is the dc current through the device. This equation is commonly referred to as the Schottky formula. Like thermal noise, shot noise is white noise and has a crest formula of approximately 4.
54.6 Flicker Noise

The imperfect contact between two conducting materials causes the conductivity to fluctuate in the presence of a dc current [1–7]. This phenomenon generates what is called flicker noise or contact noise. It is modeled by a noise current source in parallel with the device. The mean-square flicker noise current in the frequency band \( \Delta f \) is given by:

\[
\overline{i_f^2} = \frac{K_f I^m \Delta f}{f^n}
\]

(54.10)

where \( K_f \) is the flicker noise coefficient, \( I \) is the dc current, \( m \) is the flicker noise exponent, and \( n = 1 \). Other names for flicker noise are \( 1/f \) noise (read "one-over-f-noise"), low-frequency noise, and pink noise. The latter comes from the optical analog of pink light, which has a spectral density that increases at lower frequencies.

54.7 Excess Noise

In resistors, flicker noise is caused by the variable contact between particles of the resistive material and is called excess noise. Metal film resistors generate the least excess noise, carbon composition resistors generate the most, with carbon film resistors lying between the two. In modeling excess noise, the flicker noise exponent has the value \( m = 2 \). The mean-square excess noise current is often written as a function of the noise index \( NI \) as follows:

\[
\overline{i_{ex}^2} = \frac{10^{NI/10}}{10^{12} \ln 10} \times \frac{I^2 \Delta f}{f}
\]

(54.11)

where \( I \) is the dc current through the resistor. The noise index is defined as the number of \( \mu \)A of excess noise current in each decade of frequency per A of dc current through the resistor. An equivalent definition is the number of \( \mu \)V of excess noise voltage in each decade of frequency per volt of dc drop across the resistor. In this case, the mean-square excess noise voltage generated by the resistor is given by:

\[
\overline{v_{ex}^2} = \frac{10^{NI/10}}{10^{12} \ln 10} \times \frac{V^2 \Delta f}{f}
\]

(54.12)

where \( V = IR \) is the dc voltage across the resistor.

54.8 Burst Noise

Burst noise or popcorn noise is caused by a metallic impurity in a \( pn \) junction [4]. When amplified and reproduced by a loudspeaker, it sounds like corn popping. When viewed on an oscilloscope, it appears as fixed amplitude pulses of randomly varying width and repetition rate. The rate can vary from less than one pulse per minute to several hundred pulses per second. Typically, the amplitude of burst noise is 2 to 100 times that of the background thermal noise.

54.9 Partition Noise

Partition noise occurs when the charge carriers in a current have the possibility of dividing between two or more paths. The noise is generated in the resulting components of the current by the statistical process
of partition [9]. Partition noise occurs in BJTs where the current flowing from the emitter into the base can take one of two paths. The recombination of injected carriers in the base region corresponds to the current flow in one path. This current flows in the external base lead. The current carried to the collector corresponds to the current flow in the second path. Because the emitter current exhibits full shot noise, the base and collector currents also exhibit full shot noise. However, the base and collector noise currents are correlated because they have equal and opposite partition components. Partition noise in the BJT can be accounted for if all shot noise is referred to two uncorrelated shot noise current sources, one from base to emitter and the other form collector to emitter [10]. This noise model of the BJT is described here.

54.10 Generation–Recombination Noise

Generation–recombination noise is a semiconductor is generated by the random fluctuation of free carrier densities caused by spontaneous fluctuations in the generation, recombination, and trapping rates [7]. In BJTs, it occurs in the base region at low temperatures. The generation–recombination gives rise to fluctuations in the base spreading resistance which are converted into a noise voltage due to the flow of a base current. In junction FETs, it occurs in the channel at low temperatures. Generation–recombination causes fluctuations of the carrier density in the channel, which gives rise to a noise voltage when a drain current flows. In silicon junction FETs, the effect occurs below 100 K. In germanium junction FETs, it occurs at lower temperatures. The effect does not occur in MOS FETs.

54.11 Noise Bandwidth

The noise bandwidth of a filter is the bandwidth of an ideal filter having a constant passband gain which passes the same rms noise voltage, where the input signal is white noise [1–7]. The filter and the ideal filter are assumed to have the same gains. Let \( A_v(f) \) be the complex voltage gain transfer function of a filter, where \( f \) is the frequency in Hz. Its noise bandwidth \( B_n \) is given by:

\[
B_n = \frac{1}{A_{vo}} \int_0^\infty \left| A_v(f) \right|^2 \, df \tag{54.13}
\]

where \( A_{vo} \) is the maximum value of \( |A_v(f)| \). For a white noise input voltage with the spectral density \( S_v(f) \), the mean-square noise voltage at the filter output is \( v_{no}^2 = A_{vo}^2 S_v(f) B_n \).

Two classes of low-pass filters are commonly used in making noise measurements. The first has \( n \) real poles, all with the same frequency, having the magnitude-squared transfer function given by:

\[
\left| A_v(f) \right|^2 = \frac{A_{vo}^2}{1 + \left( f / f_0 \right)^n} \tag{54.14}
\]

where \( f_0 \) is the pole frequency. The second is an \( n \)-pole Butterworth filter having the magnitude-squared transfer function given by:

\[
\left| A_v(f) \right|^2 = \frac{A_{vo}^2}{1 + \left( f / f_3 \right)^{2n}} \tag{54.15}
\]
where $f_3$ is the $-3$ dB frequency. Table 54.1 gives the noise bandwidths as a function of the number of poles $n$ for $1 \leq n \leq 5$. For the real-pole filter, $B_n$ is given as a function of both $f_0$ and $f_3$. For the Butterworth filter, $B_n$ is given as a function of $f_3$.

### 54.12 Noise Bandwidth Measurement

The noise bandwidth of a filter can be measured with a white noise source with a known voltage spectral density $S_v(f)$. Let $\overline{v^2_{n2}}$ be the mean-square noise output voltage from the filter when it is driven by the noise source. The noise bandwidth is given by:

$$B_n = \frac{\overline{v^2_n}}{A_{vn}^2 S_v(f)}$$ \hspace{1cm} (54.16)

If the spectral density of the source is not known, the noise bandwidth can be determined if another filter with a known noise bandwidth is available. With both filters driven simultaneously, let $\overline{v^2_{n1}}$ and $\overline{v^2_{n2}}$ be the two mean-square noise output voltages, $B_{n1}$ and $B_{n2}$ the two noise bandwidths, and $A_{v_{n1}}$ and $A_{v_{n2}}$ the two maximum gain magnitudes. The noise bandwidth $B_{n2}$ is given by:

$$B_{n2} = B_{n1} \left( \frac{\overline{v^2_{n2}}}{\overline{v^2_{n1}}} \left( \frac{A_{v_{n1}}}{A_{v_{n2}}} \right)^2 \right)^{1/2}$$ \hspace{1cm} (54.17)

The white noise source should have an output impedance that is low enough so that the loading effect of the filters does not change the spectral density of the source.

### 54.13 Spot Noise

Spot noise is the rms noise in a band divided by the square root of the noise bandwidth. For a noise voltage, it has the units $V/\sqrt{Hz}$, which is read “volts per root Hz.” For a noise current, the units are $A/\sqrt{Hz}$. For white noise, the spot noise in any band is equal to the square root of the spectral density. Spot noise measurements are usually made with a bandpass filter having a bandwidth that is small enough so that the input spectral density is approximately constant over the filter bandwidth. The spot noise voltage at a filter output is given by $\sqrt{\overline{v^2_{n}}} / B_n$, where $\overline{v^2_{n}}$ is the mean-square noise output voltage and $B_n$ is the filter noise bandwidth. The spot noise voltage at the filter input is obtained by dividing the output voltage by $A_{vo}$, where $A_{vo}$ is the maximum value of $|A_v(f)|$.

A filter that is often used for spot noise measurements is a second-order bandpass filter. The noise bandwidth is given by $B_s = \pi B_3/2$, where $B_3$ is the $-3$ dB bandwidth. A single-pole high-pass filter having a pole frequency $f_1$ cascaded with a single-pole low-pass filter having a pole frequency $f_2$ is a special case of bandpass filter having two real poles. Its noise bandwidth is given by $B_n = \pi(f_1 + f_2)/2$. The $-3$ dB bandwidth in this case is $f_1 + f_2$, not $f_2 - f_1$.

54.14 Addition of Noise Voltages

Consider the instantaneous voltage \( v = v_n + i_n R \), where \( v_n \) is a noise voltage and \( i_n \) is a noise current. The mean-square voltage is calculated as follows:

\[
\bar{v}^2 = (v_n + i_n R)^2 = \bar{v}_n^2 + 2\rho \sqrt{\bar{v}_n^2 \bar{i}_n^2} R + \bar{i}_n^2 R^2
\]

(54.18)

where \( \rho \) is the correlation coefficient defined by:

\[
\rho = \frac{\bar{v}_n \bar{i}_n}{\sqrt{\bar{v}_n^2 \bar{i}_n^2}}
\]

(54.19)

For the case \( \rho = 0 \), the sources are said to be uncorrelated or independent. It can be shown that \(-1 \leq \rho \leq 1\).

In ac circuit analysis, noise signals are often represented by phasors. The square magnitude of the phasor represents the mean-square value at the frequency of analysis. Consider the phasor voltage \( V = V_n + I_n Z \), where \( V_n \) is a noise phasor voltage, \( I_n \) is a noise phasor current, and \( Z = R + jX \) is a complex impedance. The mean-square voltage is given by:

\[
\bar{v}^2 = (V_n + I_n \bar{Z}) \left( V_n^* + I_n^* \bar{Z}^* \right)
\]

\[
= \bar{v}_n^2 + 2\sqrt{\bar{v}_n^2 \bar{i}_n^2} \text{Re} \left( \gamma Z^* \right) + \bar{i}_n^2 \left| Z \right|^2
\]

(54.20)

where the * denotes the complex conjugate and \( \gamma \) is the complex correlation coefficient defined by:

\[
\gamma = \gamma_r + j\gamma_i = \frac{\bar{V}_n \bar{I}_n^*}{\sqrt{\bar{v}_n^2 \bar{i}_n^2}}
\]

(54.21)

It can be shown that \( |\gamma| \leq 1\).

Noise equations derived by phasor analysis can be converted easily into equations for real signals. However, the procedure generally cannot be done in reverse. For this reason, noise formulas derived by phasor analysis are the more general form.

54.15 Correlation Impedance and Admittance

The correlation impedance \( Z_\gamma \) and correlation admittance \( Y_\gamma \) between a noise phasor voltage \( V_n \) and a noise phasor current \( I_n \) are defined by [8]:

\[
Z_\gamma = R_\gamma + jX_\gamma = \gamma \sqrt{\bar{v}_n^2 \bar{i}_n^2}
\]

(54.22)

\[
Y_\gamma = G_\gamma + jB_\gamma = \gamma \sqrt{\bar{i}_n^2 \bar{v}_n^2}
\]

(54.23)

where \( \bar{v}_n^2 \) is the mean-square value of \( V_n \), \( \bar{i}_n^2 \) is the mean-square value of \( I_n \), and \( \gamma \) is the complex correlation coefficient between \( V_n \) and \( I_n \). With these definitions, it follows that \( V_n I_n^* = \bar{i}_n^2 Z_\gamma = \bar{v}_n^2 Y_\gamma^* \).
54.16 The $v_n - i_n$ Amplifier Noise Model

The noise generated by an amplifier can be modeled by referring all internal noise sources to the input [1–7], [11]. In order for the noise sources to be independent of the source impedance, two sources are required—a series voltage source and a shunt current source. In general, the sources are correlated.

Figure 54.1 shows the amplifier noise model, where $V_i$ is the source voltage, $Z_s = R_s + jX_s$ is the source impedance, $V_{ts}$ is the thermal noise voltage generated by $R_s$, $A_v = V_o/V_i$ is the complex voltage gain, and $Z_i$ is the input impedance. The output voltage is given by:

$$V_o = \frac{A_v Z_i}{Z_s + Z_i} (V_s + V_{ts} + V_n + I_n Z_s)$$  \hspace{1cm} (54.24)

The equivalent noise input voltage is the voltage in series with $V_i$ that generates the same noise voltage at the output as all noise sources in the circuit. It is given by $V_{ni} = V_n + V_n + I_n Z_s$. The mean-square value is:

$$\bar{v}_{ni}^2 = 4kTR_i + \bar{v}_{n}^2 + 2G \bar{v}_{n}^2 \gamma \bar{i}_n^2 \text{Re} \left( \gamma Z_s^* \right) + \bar{i}_n^2 |Z_s|^2$$ \hspace{1cm} (54.25)

where $B_n$ is the amplifier noise bandwidth and $\gamma$ is the complex correlation between $V_n$ and $I_n$. For $|Z_s|$ very small, $\bar{v}_{ni}^2 = \bar{v}_{n}^2$ and $\gamma$ is not important. Similarly, for $|Z_s|$ very large, $\bar{v}_{ni}^2 = \frac{\bar{i}_n^2}{Z_s^*} |Z_s|^2$ and $\gamma$ is again not important.

When the source is represented by a Norton equivalent consisting of a source current $i_s$ in parallel with a source admittance $Y_s = G_s + jB_s$, the noise referred to the input must be represented by an equivalent noise input current. The mean-square value is given by:

$$\bar{i}_{ni}^2 = 4kTG_i B_n + \bar{v}_{n}^2 |Y_s|^2 + 2G \bar{v}_{n}^2 \left| \frac{\bar{i}_n}{Y_s} \right|^2 \text{Re} \left( \gamma Y_s^* \right) + \bar{i}_n^2$$ \hspace{1cm} (54.26)

54.17 Measuring $\bar{v}_{ni}^2$, $\bar{v}_{n}^2$, and $\bar{i}_n^2$

For a given $Z_s$, the mean-square equivalent noise input voltage can be measured by setting $V_s = 0$ and measuring the mean-square noise output voltage $\bar{v}_{ni}^2$. It follows that $\bar{v}_{ni}^2$ is given by:
To measure $\overline{v_n^2}$ and $\overline{i_n^2}$, $\overline{v_m^2}$ is measured with $Z_s = 0$ and with $Z_s$ replaced by a large-value resistor. It follows that $\overline{v_n^2}$ and $\overline{i_n^2}$ are then given by:

$$\overline{v_n^2} = \overline{v_m^2} \times \frac{|A|^2}{|Z_s|^2}$$  \hspace{1cm} (54.27)

$$\overline{i_n^2} = \frac{1}{R_s} + \frac{1}{Z_s} \overline{v_m^2} \frac{|A|^2}{|Z_s|^2} \quad \text{for} \quad Z_s = R_s \quad \text{and} \quad R_s \quad \text{large}$$  \hspace{1cm} (54.29)

### 54.18 Noise Temperature

The internal noise generated by an amplifier can be expressed as an equivalent *input-termination noise temperature* [12]. This is the temperature of the source resistance that generates a thermal noise voltage equal to the internal noise generated in the amplifier when referred to the input. The noise temperature $T_n$ is given by:

$$T_n = \frac{\overline{v_m^2}}{4 k R_n} - T$$  \hspace{1cm} (54.30)

where $\overline{v_m^2}$ is the mean-square equivalent input noise voltage in the band $B_n$, $R_n$ is the real part of the source output impedance, and $T$ is the temperature of $R_n$.

### 54.19 Noise Reduction with a Transformer

Let a transformer be connected between the source and the amplifier in Figure 54.1. Let $n$ be the transformer turns ratio, $R_i$ the primary resistance, and $R_s$ the secondary resistance. The equivalent noise input voltage in series with the source voltage $V_s$ has the mean-square value:

$$\overline{v_n^2} = 4 k T \left( R_i + R_n + \frac{R_n}{n^2} \right) \Delta f + \overline{\nu_n^2}$$

$$+ 2 \sqrt{\overline{\nu_n^2} \overline{i_n^2}} \Re \left[ \gamma \left( Z_s + R_n + \frac{R_n}{n^2} \right) \right] + n^2 \overline{i_n^2} \left| Z_s + R_n + \frac{R_n}{n^2} \right|^2$$  \hspace{1cm} (54.31)

In general, $R_i/R_n \ll n$, which makes it difficult to specify the value of $n$ that minimizes $\overline{v_n^2}$. For $R_i + R_n/n^2 \ll |Z_s|$, it is minimized when:

$$n^2 = \frac{1}{|Z_s|} \overline{i_n^2} \overline{v_n^2}$$  \hspace{1cm} (54.32)
54.20 The Signal-to-Noise Ratio

The *signal-to-noise ratio* of an amplifier is defined by:

\[
\text{SNR} = \frac{\bar{v}_s^2}{\bar{v}_n^2} \quad (54.33)
\]

where \(\bar{v}_s^2\) is the mean-square signal output voltage and \(\bar{v}_n^2\) is the mean-square noise output voltage. The SNR is often expressed in dB with the equation \(\text{SNR} = 10\log\left(\frac{\bar{v}_s^2}{\bar{v}_n^2}\right)\). In measuring the SNR, a filter should be used to limit the bandwidth of the output noise to the signal bandwidth of interest. An alternative definition of the SNR that is useful in making calculations is:

\[
\text{SNR} = \frac{\bar{v}_s^2}{\bar{v}_{ni}^2} \quad (54.34)
\]

where \(\bar{v}_s^2\) is the mean-square signal input voltage and \(\bar{v}_{ni}^2\) is the mean-square equivalent noise input voltage.

54.21 Noise Factor and Noise Figure

The *noise factor* \(F\) of an amplifier is defined by [1–8]:

\[
F = \frac{\bar{v}_n^2}{\bar{v}_{no}^2} \quad (54.35)
\]

where \(\bar{v}_n^2\) is the mean-square noise output voltage with the source voltage zeroed and \(\bar{v}_{no}^2\) is the mean-square noise output voltage considering the only source of noise to be the thermal noise generated by the source resistance \(R_s\). The *noise figure* is the noise factor expressed in dB and is given by:

\[
\text{NF} = 10\log F \quad (54.36)
\]

For the \(v_n - i_n\) amplifier noise model, the noise factor is given by:

\[
F = \frac{\bar{v}_{mi}^2}{4kT R B_n} = 1 + \frac{\bar{v}_n^2 + 2\sqrt{\bar{v}_n^2\bar{i}_n^2} \text{Re}\left\{\gamma Z_i^\prime\right\} + \bar{i}_n^2 |Z_i^\prime|^2}{4kT R B_n} \quad (54.37)
\]

where \(B_n\) is the amplifier noise bandwidth. The value of \(Z_i^\prime\) that minimizes the noise figure is called the *optimum source impedance* and is given by:

\[
Z_{so} = R_{so} + jX_{so} = \left[1 - \gamma_i^\prime - j\gamma_i^\prime\right] \sqrt{\frac{\bar{v}_n^2}{\bar{i}_n^2}} \quad (54.38)
\]

where \(\gamma_i = \text{Im}\left(\gamma_i^\prime\right)\). The corresponding value of \(F\) is denoted by \(F_0\) and is given by:
\[ F_0 = 1 + \frac{\sqrt{\gamma_n^2 + \gamma_i^2}}{2kTB_n} \left( \gamma_r + j\sqrt{\gamma_r^2 - 1} \right) \]  

(54.39)

It follows that \( F \) can be expressed in terms of \( F_0 \) as follows:

\[ F = F_0 + \frac{G_n}{R_{ns}} \left[ (R - R_{sn})^2 + (X_s - X_{sn})^2 \right] \]  

(54.40)

where \( G_n \) is the noise conductance of \( I_n \) and \( R_{sn} \) is the noise resistance of the source. These are given by:

\[ G_n = \frac{\bar{i}_n^2}{4kTB_n} \]  

(54.41)

\[ R_{sn} = \frac{\bar{v}_n^2}{4kTB_n} = \frac{TR}{T_0} \]  

(54.42)

When the source is represented by a Norton equivalent consisting of a source current \( i_s \) in parallel with a source admittance \( Y_s = G_s + jB_s \), the optimum source admittance is given by:

\[ Y_{so} = G_{so} + jB_{so} = \left[ \sqrt{\gamma_r^2 + \gamma_i^2 + \gamma_i^2} \right] \left( \frac{\bar{i}_s^2}{\bar{v}_n^2} \right) \]  

(54.43)

which is the reciprocal of \( Z_{so} \). The noise factor can be written as:

\[ F = F_0 + \frac{R}{G_{ns}} \left[ (G_s - G_{ns})^2 + (B_s - B_{ns})^2 \right] \]  

(54.44)

where \( R_n \) is the noise resistance of \( V_n \) and \( G_{ns} \) is the noise conductance of the source. These are given by:

\[ R_n = \frac{\bar{v}_n^2}{4kTB_n} \]  

(54.45)

\[ G_{ns} = \frac{\bar{i}_s^2}{4kTB_n} = \frac{TG_s}{T_0} \]  

(54.46)

### 54.22 Noise Factor Measurement

The noise factor can be measured with a calibrated white noise source driving the amplifier. The source output impedance must equal the value of \( Z_s \) for which \( F \) is to be measured. The source temperature
must be the standard temperature $T_0$. First, measure the amplifier noise output voltage over the band of interest with the source voltage set to zero. For the amplifier model of Figure 54.1, the mean-square value of this voltage is given by:

$$
\overline{v_n^2} = \left| \frac{A_m Z_s}{Z_s + Z_i} \right|^2 \left[ 4kT_0 R_B + \overline{v_n^2} + 2\sqrt{\overline{v_n^2}} \sqrt{\overline{i_n^2}} \text{Re}\left(\gamma Z_s^*\right) + i_n^2 Z_s^* \right] \tag{54.47}
$$

The source noise voltage is then increased until the output voltage increases by a factor $r$. The new mean-square output voltage can be written as:

$$
r^2 \overline{v_n^2} = \left| \frac{A_m Z_s}{Z_s + Z_i} \right|^2 \left[ (S_s(f) + 4kT_0 R_B) B_n + \overline{v_n^2} + 2\sqrt{\overline{v_n^2}} \sqrt{\overline{i_n^2}} \text{Re}\left(\gamma Z_s^*\right) + i_n^2 Z_s^* \right] \tag{54.48}
$$

where $S_s(f)$ is the open-circuit voltage spectral density of the white noise source.

The above two equations can be solved for $F$ to obtain:

$$
F = \frac{S_s(f)}{(r^2 - 1)4kT_0 R_B} \tag{54.49}
$$

A common value for $r$ is $\sqrt{2}$. The gain and noise bandwidth of the amplifier are not needed for the calculation. If a resistive voltage divider is used between the noise source and the amplifier to attenuate the input signal, the source spectral density $S_s(f)$ is calculated or measured at the attenuator output with it disconnected from the amplifier input.

If the noise bandwidth of the amplifier is known, its noise factor can be determined by measuring the mean-square noise output voltage $\overline{v_n^2}$ with the source voltage set to zero. The noise factor is given by:

$$
F = 1 + \left| Z_s \right|^2 \frac{\overline{v_{no}^2}}{4kT_0 R_B B_n A_{no}^2} \tag{54.50}
$$

This expression is often used with $B_n = \pi B_3/2$, where $B_3$ is the $–3$ dB bandwidth. Unless the amplifier has a first-order low-pass or a second-order bandpass frequency response characteristic, this is only an approximation.

### 54.23 The Junction Diode Noise Model

When forward biased, a diode generates both shot noise and flicker noise [1–7]. The noise is modeled by a parallel current source having the mean-square value:

$$
\overline{i_n^2} = 2qI\Delta f + \frac{K_i I^* \Delta f}{f} \tag{54.51}
$$

where $I$ is the dc diode current. A plot of $\overline{i_n^2}$ vs. $f$ for a constant $\Delta f$ exhibits a slope of $–10$ dB/decade for low frequencies and a slope of zero for higher frequencies.

Diodes are often used as noise sources in circuits. Specially processed zener diodes are marketed as solid-state noise diodes. The noise mechanism in these is called avalanche noise, which is associated with
the diode reverse breakdown current. For a given breakdown current, avalanche noise is much greater than shot noise in the same current.

54.24 The BJT Noise Model

Figure 54.2(a) shows the BJT noise model [1–7]. The base spreading resistance \( r_b \) is modeled as an external resistor; \( v_{tx} \) is the thermal noise generated by \( r_b \); \( i_{shb} \) and \( i_{fb} \) respectively, are the shot noise and flicker noise in the base bias current \( I_B \); and \( i_{shc} \) is the shot noise in the collector bias current \( I_C \). The sources have the mean-square values of:

\[
\overline{v_{tx}^2} = 4kT r_b \Delta f
\]

\[
\overline{i_{shb}^2} = 2qI_b \Delta f
\]

\[
\overline{i_{fb}^2} = \frac{K_f I_b^2 \Delta f}{f}
\]

\[
\overline{i_{shc}^2} = 2qI_c \Delta f
\]

Let the resistances to signal ground seen looking out of the base and the emitter, respectively, be denoted by \( R_1 \) and \( R_2 \). The mean-square equivalent noise input voltages in series with the base or the emitter that generates the same collector noise current is given by:

\[
\overline{v_{ni}^2} = 4kT \left( R_1 + r_b + R_2 \right) \Delta f + \left( 2qI_b \Delta f + \frac{K_f I_b \Delta f}{f} \right) \left( R_1 + r_b + R_2 \right)^2
\]

\[
+ 2qI_c \Delta f \left( \frac{R_1 + r_b + R_2}{\beta} + \frac{V_T}{I_c} \right)^2
\]
At frequencies where flicker noise can be neglected, the value of $I_c$ that minimizes $\bar{v}_{ni}^2$ is called the \textit{optimum collector current}. It is given by:

$$I_{c_{\text{opt}}} = \frac{V_T}{R_f + r_x + R_2} \times \frac{\beta}{\sqrt{1+\beta}}$$  \hfill (54.57)

The corresponding value of $\bar{v}_{ni}^2$ is given by:

$$\bar{v}_{ni}^2 = 4kT \left( R_f + r_x + R_2 \right) \Delta f \times \frac{\sqrt{1+\beta}}{\sqrt{1+\beta} - 1}$$  \hfill (54.58)

If $N$ identical BJTs that are identically biased are connected in parallel, the equivalent noise input voltage is given by Equation 54.56 with $r_x$ replaced with $r_x/N$, $I_b$ replaced with $NI_b$, and $I_c$ replaced with $NI_c$. In this case, $R_f$ and $R_2$, respectively, are the resistances to signal ground seen looking out of the parallel connected bases and the parallel connected emitters. For $N$ fixed, the value of $I_c$ that minimizes $\bar{v}_{ni}^2$ is given by Equation 54.57 with $r_x$ replaced with $NR_x$ and $R_2$ replaced with $NR_2$. The corresponding value of $\bar{v}_{ni}^2$ is given by Equation 54.58 with $r_x$ replaced with $r_x/N$. It follows that parallel connection of BJTs can be used to reduce the thermal noise of $r_x$, provided the devices are optimally biased.

The BJT $v_n - i_n$ noise model is given in Figure 54.2(b), where $r_x$ is a noiseless resistor, for its thermal noise is included in $v_n$. The mean-square values of $v_n$ and $i_n$ and the correlation coefficient are given by:

$$\overline{v_n^2} = 4kT \tau \Delta f + 2kT \frac{V_T}{I_c} \Delta f$$  \hfill (54.59)

$$\overline{i_n^2} = 2qI_b \Delta f + \frac{K_T I^0_b \Delta f}{f} + 2qI_b \Delta f \beta^2$$  \hfill (54.60)

$$\rho = \frac{2kT \Delta f}{\beta \overline{v_n^2} \overline{i_n^2}}$$  \hfill (54.61)

where $\beta = I_c/I_b$ is the current gain. An alternative model puts $r_x$ inside the BJT. For this model, the expressions for $i_n$ and $\rho$ are more complicated than the ones given here.

The $v_n - i_n$ noise model of Figure 54.1 does not have a noiseless resistor in series with its input. Before formulae that are derived for this model are applied to the BJT model of Figure 54.2(b), the formulae must be modified to account for the noiseless $r_x$. For the common-emitter amplifier, for example, the source resistance $R_s$ would be replaced in the expression for $\overline{v_n^2}$ by $R_f + r_x$ in all occurrences except in terms that represent the thermal noise of $R_f$.

The value of the base spreading resistance $r_x$ depends on the method used to measure it. For noise calculations, $r_x$ should be measured with a noise technique. A test circuit for measuring $r_x$ is shown in Figure 54.3. The emitter bias current $I_e$ and the collector bias voltage $V_C$ are given by:

$$I_e = \frac{-V_{BE} - V_{EE}}{R_E}$$  \hfill (54.62)

$$V_C = V_{CC} - \alpha I_e R_C$$  \hfill (54.63)
where $\alpha = \beta/(1 + \beta)$. Capacitors $C_1$ and $C_2$ should satisfy $C_1 >> I_E/(2\pi f V_T)$ and $C_2 >> 1/(2\pi f R_C)$, where $f$ is the lowest frequency of interest. To minimize the noise contributed by $R_C$, $R_F$, and the op-amp, a low-noise op-amp should be used and $R_F$ should be much larger than $R_C$. The power supply rails must be properly decoupled to minimize power supply noise.

To prevent flicker noise from affecting the data, the op-amp output voltage must be measured over a noise bandwidth where the spectral density is white. Denote the mean-square op-amp output voltage over the band $B_n$ with the BJT in the circuit by $v_{no1}^2$. Denote the mean-square voltage over the band $B_n$ with the BJT removed by $v_{no2}^2$. The base spreading resistance $r_x$ can be obtained by solving:

$$r_x^2 \left[ \frac{A}{\beta^2} - 2qI_B B_n \right] + r_x \left[ \frac{2AV_T}{\beta I_C} - 4kTB_n \right] + \frac{AV_T^2}{I_C^2} = 0 \quad (54.64)$$

Where:

$$A = \frac{v_{no1}^2 - v_{no2}^2}{R_F^2} - 2qI_B B_n \quad (54.65)$$

The test circuit of Figure 54.3 can be used to measure the flicker noise coefficient $K_f$ and the flicker noise exponent $m$. The plot of $(v_{no1}^2 - v_{no2}^2)$ vs. frequency for a constant noise bandwidth $\Delta f$ must be obtained, e.g., with a signal analyzer. In the white noise range, the slope of the plot is zero. In the flicker noise range, the slope is $-10$ dB per decade. The lower frequency at which $(v_{no1}^2 - v_{no2}^2)$ is 3 dB greater than its value in the white noise range is the flicker noise corner frequency $f_f$. It can be shown that:

$$K_f I_f^m = \frac{(v_{no1}^2 - v_{no2}^2)}{2R_C^2} f_f \cdot \left( \frac{r_x}{\beta} + \frac{V_T}{I_C} \right)^2$$

$$\quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad (54.66)$$
By repeating the measurements for at least two values of \( I_c \), this equation can be used to solve for both \( K_f \) and \( m \). Unless \( I_c \) is large, the \( r_x / b \) term can usually be neglected compared to the \( V_T / I_c \) term. The value of the flicker noise exponent is usually in the range \( 1 < m < 3 \), but is often taken as unity. If it is assumed that \( m = 1 \), the value of \( K_f \) can be calculated by making the measurements with only one value of \( I_c \).

54.25 The FET Noise Model

Figure 54.4(a) shows the MOSFET noise equivalent circuit, where \( i_{td} \) is the channel thermal noise current and \( i_{fd} \) is the channel flicker noise current \([1–7]\). The mean-square values of these currents are given by:

\[
\overline{i_{td}^2} = \frac{8kT\Delta f}{3g_m}
\]  

(54.67)

\[
\overline{i_{fd}^2} = \frac{K_i\Delta f}{4KfE \, C_{ox}}
\]  

(54.68)

where \( K \) is the transconductance parameter, \( g_m = 2\sqrt{KI_D} \) is the transconductance, \( L \) is the effective length of the channel, and \( C_{ox} \) is the gate oxide capacitance per unit area.

Let the resistances to signal ground seen looking out of the gate and the source, respectively, be denoted by \( R_1 \) and \( R_2 \). The mean-square equivalent noise input voltage in series with either the gate or the source that generates the same drain noise current is given by:

\[
\overline{v_n^2} = 4kT\left(R_1 + R_2\right)\Delta f + \frac{4kT\Delta f}{3\sqrt{KI_D}} + \frac{K_i\Delta f}{4KfE \, C_{ox}} f
\]  

(54.69)

where it is assumed that the MOSFET bulk is connected to its source in the ac circuit. If \( N \) identical MOSFETs that are identically biased are connected in parallel, the equivalent noise input voltage is given by Equation 54.69 with the exception that the second and third terms are divided by \( N \).

The noise sources in Figure 54.4(a) can be reflected into a single source in series with the gate. The circuit is shown in Figure 54.4(b). The mean-square value of \( v_n \) is given by:

\[
\overline{v_n^2} = \frac{8kT\Delta f}{3g_m} + \frac{K_i\Delta f}{4KfE \, C_{ox}}
\]  

(54.70)
The FET flicker noise coefficient $K_f$ can be measured by replacing the BJT in Figure 54.3 with the FET. On a plot of $\left( \frac{v_{n1}^2}{v_{n2}^2} \right)$ as a function of frequency for a constant noise bandwidth, the flicker noise corner frequency $f_f$ is the lower frequency at which $\left( \frac{v_{n1}^2}{v_{n2}^2} \right)$ is up 3 dB above the white noise level. A signal analyzer can be used to display this plot. The flicker noise coefficient is given by:

$$K_f = \frac{32kT f_f^2 E C_{ox}}{3g_m}$$

(54.71)

The MOSFET circuits and equations also apply to the junction FET with the exception that the $L^2$ and $C_{ox}$ terms are omitted from the formulae. This assumes that the junction FET gate-to-channel junction is reverse biased, which is the usual case. Otherwise, shot noise in the gate current must be modeled.

### 54.26 Operational Amplifier Noise Models

Variations of the $v_n - i_n$ amplifier noise model are used in specifying op-amp noise performance. The three most common models are given in Figure 54.5. In Figures 54.5(b) and (c), $v_n$ can be placed in series with either input [4, 6]. In general, the sources in each model are correlated. In making calculations that use specified op-amp noise data, it is important to use the noise model for which the data apply.

### 54.27 Photodiode Detector Noise Model

Figure 54.6(a) shows the circuit symbol of a photodiode detector [4]. When reverse biased by a dc source, an incident light signal causes a signal current to flow in the diode. The diode small-signal noise model is shown in Figure 54.6(b), where $i_s$ is the signal current (proportional to the incident light intensity), $i_n$ is the diode noise current, $r_d$ is the small-signal resistance of the reverse-biased junction, $C_i$ is the small-signal junction capacitance, $r_c$ is the cell resistance (typically <50 Ω), and $v_{tc}$ is the thermal noise voltage.

© 1999 by CRC Press LLC
The noise current $i_n$ consists of three components: shot noise $i_{sh}$, flicker noise $i_f$, and carrier generation–recombination noise $i_{gr}$. The first three have the mean-square values:

$$\overline{v_{tc}^2} = 4kTc\Delta f$$  \hspace{1cm} (54.72)$$

$$\overline{i_{sh}^2} = 2qI_D\Delta f$$  \hspace{1cm} (54.73)$$

$$\overline{i_f^2} = \frac{K_f I_{nm}^2 \Delta f}{f}$$  \hspace{1cm} (54.74)$$

where $I_D$ is the reverse-biased diode current. The carrier generation–recombination noise has a white spectral density up to a frequency determined by the carrier lifetime. Because the detector has a large output resistance, it should be used with amplifiers that exhibit a low input current noise.

## 54.28 Piezoelectric Transducer Noise Model

Figure 54.7(a) shows the circuit symbol of a piezoelectric transducer [4]. This transducer generates an electric voltage when a mechanical force is applied between two of its surfaces. An approximate equivalent circuit that is valid for frequencies near the transducer mechanical resonance is shown in Figure 54.7(b). In this circuit, $C_e$ represents the transducer electric capacitance, while $C_s$, $L_s$, and $R_s$ are chosen to have a resonant frequency and quality factor numerically equal to those of the transducer mechanical resonance. The source $v_s$ represents the signal voltage, which is proportional to the applied force. The source $v_{ts}$ represents the thermal noise generated by $R_s$. It has a mean-square value of:

$$\overline{v_{ts}^2} = 4kTR_s\Delta f$$  \hspace{1cm} (54.75)$$

This noise component is negligible in most applications.

The piezoelectric transducer has two resonant frequencies: a short-circuit resonant frequency $f_s$ and an open-circuit resonant frequency $f_{oc}$ given by:
where \( C_1 = C_s C_e / (C_s + C_e) \). It is normally operated at the open-circuit resonant frequency where the transducer output impedance is very high. For this reason, it is should be used with amplifiers that exhibit a low input current noise.

54.29 Parametric Amplifiers

A parametric amplifier is an amplifier that uses a time varying reactance to produce amplification [13]. In low-noise microwave parametric amplifiers, a reverse biased \( pn \) junction diode is used to realize a variable capacitance. Such diodes are called varactors, for variable reactance. The depletion capacitance of the reverse-biased junction is varied by simultaneously applying a signal current and a pump current at different frequencies. The nonlinear capacitance causes frequency mixing to occur between the signal frequency and the pump frequency. When the power generated by the frequency mixing exceeds the signal input power, the diode appears to have a negative resistance and signal amplification occurs. The only noise that is generated is the thermal noise of the effective series resistance of the diode, which is very small.

Figure 54.8 shows block diagram of a typical parametric amplifier. The varactor diode is placed in a resonant cavity. A circulator is used to isolate the diode from the input and output circuits. A pump signal is applied to the diode to cause its capacitance to vary at the pump frequency. The filter isolates the pump signal from the output circuit. The idler circuit is a resonant cavity that is coupled to the diode.
cavity to reduce the phase sensitivity. Let the signal frequency be $f_s$, the pump frequency be $f_p$, and the resonant frequency of the idler cavity be $f_i$. In cases where $f_p = f_s + f_i$, the varying capacitance of the diode looks like a negative resistance and the signal is amplified. If $f_i = f_s$, the amplifier is called a *degenerate* amplifier. This is the simplest form of the parametric amplifier and it requires the lowest pump frequency and power to operate. For the *nondegenerate* amplifier, $f_p > 2f_s$. In both cases, the input and the output are at the same frequency. In the *up-converter* amplifier, $f_p = f_i - f_s$ and $f_p > 2f_s$. In this case, the varying capacitance of the diode looks like a positive resistance and the signal frequency output is not amplified. However, there is an output at the idler frequency that is amplified. Thus, the output frequency is higher than the input frequency. The conversion gain can be as high as the ratio of the output frequency to the input frequency.

### 54.30 Measuring Noise

A typical setup for measuring noise is shown in Figure 54.9. To prevent measurement errors caused by signals coupling in through the ground and power supply leads, the circuit under test and the test set must be properly grounded and good power supply decoupling must be used [6]. For measurement schemes requiring a sine-wave source, an internally shielded oscillator is preferred over a function generator. This is because function generators can introduce errors caused by radiated signals and signals coupled through the ground system.

When making measurements on a high-gain circuit, the input signal must often be attenuated. Attenuators that are built into sources might not be adequately shielded, so that errors can be introduced by radiated signals. These problems can be minimized if a shielded external attenuator is used between the source and the circuit under test. Such an attenuator is illustrated in Figure 54.9. When a high attenuation is required, a multi-stage attenuator is preferred. For proper frequency response, the attenuator might require frequency compensation [4]. Unless the load impedance on the attenuator is large compared to its output impedance, both the attenuation and the frequency compensation can be a function of the load impedance.
Figure 54.9 shows a source impedance $Z_s$ in series with the input to the circuit under test. This impedance is in series with the output impedance of the attenuator. It must be chosen so that the circuit under test has the desired source impedance termination for the noise measurements.

Because noise signals are small, a low-noise amplifier is often required to boost the noise level sufficiently so that it can be measured. Such an amplifier is shown in Figure 54.9. The noise generated by the amplifier will add to the measured noise. To correct for this, first measure the mean-square noise voltage with the amplifier input terminated in the output impedance of the circuit under test. Then subtract this from the measured mean-square noise voltage with the circuit under test driving the amplifier. The difference is the mean-square noise due to the circuit. Ideally, the amplifier should have no effect on the measured noise.

The noise voltage over a band can be measured with either a spectrum analyzer or with a filter having a known noise bandwidth and a voltmeter. The noise can be referred to the input of the circuit under test by dividing by the total gain between its input and the measuring device. The measuring voltmeter should have a bandwidth that is at least 10 times the noise bandwidth of the filter. The voltmeter crest factor is the ratio of the peak input voltage to the full-scale rms meter reading at which the internal meter circuits overload. For a sine-wave signal, the minimum voltmeter crest factor is $\sqrt{2}$. For noise measurements, a higher crest factor is required. For gaussian noise, a crest factor of 3 gives an error less than 1.5%. A crest factor of 4 gives an error less than 0.5%. To avoid overload on noise peaks caused by an inadequate crest factor, measurements should be made on the lower one-third to one-half of the voltmeter scale.

A true rms voltmeter is preferred over one that responds to the average rectified value of the input voltage but is calibrated to read rms. When the latter type of voltmeter is used to measure noise, the reading will be low. For gaussian noise, the reading can be corrected by multiplying the measured voltage by 1.13. Noise voltages measured with a spectrum analyzer must also be corrected by the same factor if the spectrum analyzer responds to the average rectified value of the input voltage but is calibrated to read rms.

Noise measurements with a spectrum analyzer require a knowledge of the noise bandwidth of the instrument. For a conventional analyzer, the bandwidth is proportional to frequency. When white noise
is analyzed, the display exhibits a slope of +10 dB per decade. However, the measured voltage level at any frequency divided by the square root of the noise bandwidth of the analyzer is a constant equal to the spot-noise value of the input voltage at that frequency. Bandpass filters that have a bandwidth proportional to the center frequency are called constant-Q filters. For a second-order constant-Q filter, the noise bandwidth is given by \( B_n = \pi f_0/2Q \), where \( f_0 \) is the center frequency and \( Q \) is the quality factor. The latter is given by \( Q = f_0/B_n \), where \( B_n \) is the \(-3\) dB bandwidth. These equations are often used to estimate the noise bandwidth of bandpass filters that are not second order.

A second type of spectrum analyzer is called a signal analyzer. Such an instrument uses digital signal processing techniques to calculate the spectrum of the input signal as a discrete Fourier transform. The noise bandwidth of these instruments is a constant so that the display exhibits a slope of zero when white noise is the input signal.

Fairly accurate rms noise measurements can be made with an oscilloscope. A filter should be used to limit the noise bandwidth at its input. Although the procedure is subjective, the rms voltage can be estimated by dividing the observed peak-to-peak voltage by 6 \([4]\). One of the advantages of using the oscilloscope is that non-random noise that can affect the measurements can be identified, e.g., a 60-Hz hum signal.

Another oscilloscope method is to display the noise simultaneously on both inputs of a dual-channel oscilloscope that is set in the dual-sweep mode. The two channels must be identically calibrated and the sweep rate must be set low enough so that the displayed traces appear as bands. The vertical offset between the two bands is adjusted until the dark area between them just disappears. The rms noise voltage is then measured by grounding the two inputs and reading the vertical offset between the traces.

**Defining Terms**

**Burst noise**: Noise caused by a metallic impurity in a \textit{pn} junction that sounds like corn popping when amplified and reproduced by a loudspeaker. Also called popcorn noise.

**Crest factor**: The ratio of the peak value to the rms value.

**Equivalent noise input current**: The noise current in parallel with an amplifier input that generates the same noise voltage at its output as all noise sources in the amplifier.

**Equivalent noise input voltage**: The noise voltage in series with an amplifier input that generates the same noise voltage at its output as all noise sources in the amplifier.

**Equivalent noise resistance (conductance)**: The value of a resistor (conductance) at the standard temperature \( T_0 = 290 \) K that generates the same mean-square noise voltage (current) as a source.

**Excess noise**: Flicker noise in resistors.

**Flicker noise**: Noise generated by the imperfect contact between two conducting materials causing the conductivity to fluctuate in the presence of a dc current. Also called contact noise, 1/f noise, and pink noise.

**Generation-recombination noise**: Noise generated in a semiconductor by the random fluctuation of free carrier densities caused by spontaneous fluctuations in the generation, recombination, and trapping rates.

**Noise bandwidth**: The bandwidth of an ideal filter having a constant passband gain that passes the same rms noise voltage as a filter, where the input signal is white noise.

**Noise factor**: The ratio of the mean-square noise voltage at an amplifier output to the mean-square noise voltage at the amplifier output considering the thermal noise of the input termination to be the only source of noise.

**Noise figure**: The noise factor expressed in dB.

**Noise index**: The number of \( \mu A \) of excess noise current in each decade of frequency per A of dc current through a resistor. Also, the number of \( \mu V \) of excess noise voltage in each decade of frequency per V of dc voltage across a resistor.

**Noise temperature**: The internal noise generated by an amplifier expressed as an equivalent input-termination noise temperature.
Nyquist formula: Expression for the mean-square thermal noise voltage generated by a resistor.

Optimum source impedance (admittance): The complex source impedance (admittance) that minimizes the noise factor.

Parametric amplifier: An amplifier that uses a time-varying reactance to produce amplification.

Partition noise: Noise generated by the statistical process of partition when the charge carriers in a current have the possibility of dividing between two or more paths.

Shot noise: Noise caused by the random emission of electrons and by the random passage of charge carriers across potential barriers.

Schottky formula: Expression for the mean-square shot noise current.

Signal-to-noise ratio: The ratio of the mean-square signal voltage to the mean-square noise voltage at an amplifier output.

Spectral density: The mean-square value per unit bandwidth of a noise signal.

Spot noise: The rms noise in a band, divided by the square root of the noise bandwidth.

Thermal noise: Noise generated by the random collision of charge carriers with a lattice under conditions of thermal equilibrium. Also called Johnson noise.

Varactor diode: A diode used as a variable capacitance.

Voltmeter crest factor: The ratio of the peak input voltage to the full-scale rms meter reading at which the internal meter circuits overload.

White noise: Noise that has a spectral density that is flat, i.e., not a function of frequency.

References

Further Information

Microwave measurements cover the frequency range from 0.5 GHz to about 20 GHz. Frequencies from 30 GHz to 300 GHz are often referred to as mm-waves. In the following, the most important measurements are described.

### 55.1 Power Measurement

Exact microwave power measurement is in demand for development, fabrication, and installation of modern telecommunication networks. It is essential for attenuation, insertion, and return loss measurements, as well as for noise measurement and six-port network analysis. This chapter gives a brief overview about the basics of microwave power measurement. Detailed information about this subject can be found in [1–4]. Power detectors usually consist of a sensor that transfers the microwave signal into a dc or low-frequency signal and a power meter to read out the measured power levels. The sensor includes a load impedance for the microwave source (Figure 55.1).

First, several power definitions need to be clarified:

- **Conjugate available power** ($P_{CA}$): The maximum available power a signal generator can transmit. This power is delivered by the generator if the load impedance is equal to the complex conjugate of the generator’s source impedance. Since measurement techniques often require different lengths of waveguides or coaxial lines, the conjugate available power can be achieved only by tuning.

- **$Z_0$ Available power** ($P_{Z0}$): The power that is transferred via a coaxial line of characteristic impedance $Z_0$ into a load impedance $Z_L$ equal to $Z_0$, while the generator has the impedance $Z_G$. Consequently, the available power level is reduced due to generator mismatch: $P_{Z0} = P_{CA}(1 - |\Gamma_c|^2)$, where $\Gamma_c$ is
the reflection coefficient of the generator. Figure 55.2 shows the relationships between $P_{CA}$, $P_{Z_0}$ and the maximum and minimum power levels that can be measured in the load of a power sensor.

- **Average power ($P_{av}$):** The result of an averaging over many periods of the lowest modulation frequency of a modulated signal $P(t)$ (Figure 55.3).
- **Envelope power ($P_e(t)$):** The power averaged over the period of the carrier frequency.
- **Peak envelope power (PEP):** The maximum of $P_e(t)$.
- **Pulse power ($P_P$):** Defined for pulsed signals. If the pulse width $\tau$ and the repetition frequency $1/T$ is known, $P_P$ is given by the measured average power:

$$P_P = P_{av} \frac{T}{\tau}$$

**Measurement Errors and Uncertainties**

Measurement errors occur due to mismatch as well as inside the power sensor and in the power meter. After correcting for these errors, the measurement uncertainties remain. Typically 75% of the total

---

FIGURE 55.1 Setup of a power measurement in load configuration.

FIGURE 55.2 Relationships between conjugate power $P_{CA}$, $Z_0$, available power $P_{Z_0}$ and the power levels available in the load of the power sensor.
uncertainty belongs to mismatch and the smallest part is due to the power meter. The uncertainties and errors can be power dependent, frequency dependent, or independent of both. Of course, the total uncertainty must be calculated from the different uncertainties \( u_i \) as the root-sum-of-the-squares: \( \text{rss} = \sqrt{\sum u_i^2} \), provided that the errors are all independent. A pessimistic error definition is the worst-case uncertainty, which simply sums up all extreme values of the independent errors.

Mismatch errors occur due to the fact that neither the generator (G), the line, nor the load (L) exhibit exactly the characteristic impedance \( Z_0 \). Using the modulus of the reflection coefficient \( |\Gamma| \), the available power of the generator \( P_G \) can be expressed as [3]:

\[
\begin{align*}
P_G &= P_t \frac{|1 - \Gamma_G \Gamma_L|^2}{(1 - |\Gamma_G|^2)(1 - |\Gamma_L|^2)} \\
\end{align*}
\]  

(55.1)

The reflection coefficients can also be expressed in terms of the voltage standing wave ratio (VSWR):

\[
|\Gamma| = \frac{\text{VSWR} - 1}{\text{VSWR} + 1} = \frac{Z_L - Z_0}{Z_L + Z_0} \tag{55.2}
\]

As mentioned, the knowledge of \( Z_0 \) available power \( P_{Z0} \) is sufficient in most applications. Then the ratio between the \( Z_0 \) available power and the absorbed power is given by:

\[
\frac{P_{Z0}}{P_t - P_f} = \frac{|1 - \Gamma_G \Gamma_L|^2}{1 - |\Gamma_L|^2} \tag{55.3}
\]
where the subscripts “i” and “r” denote the incident and reflected power, respectively. Expressing Equation 55.3 in dB gives the $Z_0$ mismatch loss while the term $-10 \log(1 - |\Gamma_i|^2)$ is called the mismatch loss, which accounts for reflected power from the load only.

Since the reflection coefficients are seldomly known completely but only their magnitudes are known, a mismatch uncertainty is defined as:

$$M_u = \left\{ \left( 1 \pm |\Gamma_0||\Gamma_1| \right)^2 - 1 \right\} \times 100\%$$  \hspace{1cm} (55.4)

**Conversion errors** are due to the specific characteristics of the individual power sensor. The conversion efficiency is frequently dependent and a calibration factor (CF) is defined for each power detector:

$$CF = \frac{P_u}{P_i}$$  \hspace{1cm} (55.5)

where $P_u$ is the uncorrected power and $P_i$ is the actual incident power (Figure 55.1). Sometimes also the effective efficiency $\eta_e$ is used:

$$\eta_e = \frac{P_u}{P_i - P_i}$$  \hspace{1cm} (55.6)

Both quantities are related via the reflection coefficient of the load of the power sensor:

$$CF = \eta_e \left(1 - |\Gamma_1|^2\right)$$  \hspace{1cm} (55.7)

The calibration factor is used to correct for efficiency loss and it also accounts for the mismatch loss. Still a remaining calibration factor uncertainty has to be taken into account. It is specified for each sensor. The calibration data are usually traceable to a national bureau of standards. Power sensors under test can be compared to the standards using high directivity couplers or power splitters [2].

The next described errors are due to the electronics inside the power meter.

Some power meters exhibit an internal reference oscillator to verify and adjust for the sensitivity of the diode or thermocouple sensor. The reference power uncertainty is specified by the manufacturer. Since this reference has its own reflection coefficient, it is related to a reference oscillator mismatch uncertainty.

**Instrumentation uncertainty** depends on the circuit limitations of the power meter and is specified by the manufacturer.

The ±1 Count Error is for digital output and can be expressed by the relative power reading of the last significant digit.

Autozero can be used on all measurement ranges. Zero-setting immediately prior to the measurement can reduce drift errors when measuring in the lower ranges. Still zero set errors remain due to noise during the zero-setting operation. This error can be very serious for measurement of low power levels [5]. Zero carryover is caused by ADC quantization errors in the zero readings for all measurement ranges except the most sensitive one. ADC quantization also causes a power quantization error. If very low power levels have to be measured, averaging can reduce random noise at the expense of measurement speed.

**Power Sensors**

A large variety of power sensors is available for the frequency range from dc up to 110 GHz and for minimum detectable power levels as low as 100 pW. The sensors differ in measurement principle and
hence the correct choice depends on the application. A detailed description of power sensors is given in [2, 3]. Thermal sensors transform the absorbed microwave power into heat that is measured with temperature-sensitive elements:

- **Calorimeters** measure the heat absorbed in a fluid (e.g., water) of well-known specific heat. Applying the substitution principle, their precision can be enhanced. Because of their high stability, they are used in the National Institute of Standards. The manufacturer usually references the sensors to these standards.

- **Bolometers** and **thermistors** [3] make use of the temperature-dependent resistivity change of a resistive load, which is highly nonlinear. Hence, dc power substitution is used to keep the load at constant temperature. The substituted dc power is the measurement. Self-balancing bridges are used for this purpose but need careful ambient temperature compensation. The effective efficiency of bolometers is known very exactly. However, they have only relatively small dynamic range (typical 10 μW to 10 mW). Currently, liquid nitrogen-cooled, high-temperature superconducting bolometers with extremely high sensitivity of several thousands volts per watt are used [6]. A comprehensive overview of bolometers if given in [7].

- **Thermocouple sensors** are based on microwave power conversion into heat via a matched load impedance. Its temperature is controlled by thermocouples utilizing the thermoelectric effect in thin films or semiconductors [8]. One has to distinguish between realizations where the thermocouple itself represents the load impedance [3] and galvanically decoupled thermocouples [9]. The main advantages of the latter sensors are the better flatness of the response from dc to microwave and a lower VSWR. The design of such sensors is simple and a silicon micromachining technique can be applied to enhance the sensitivity [10]. The lowest measurable power levels are 1 μW.

Thermal sensors are well-suited to absolute power measurement, especially with respect to their high linearity. Their drawback is the relatively long response time (>10 ms), which limits these sensors to the measurement of average power. The high speed of Schottky diodes predestines them for the measurement of peak power, envelope power, and peak envelope power.

- **Diode sensors** consist of Schottky barrier diodes that are zero-biased and work in the square-law part of their I–V characteristics. For low power levels (<–20 dBm), these devices are very linear in response and measure the average power correctly. Still, diode sensors exhibit nonquadratic contributions [11], which can be important to account for when accurate measurement is required. Minimum detectable power is ~70 dBm where the signal level is of the order of 50 nV and requires sophisticated amplification. The diode sensor is part of the sensors described below.

- **Peak power sensors** are specially designed for peak power measurements and account for measurement errors due to waveform and power level, although any diode detector can be used for this purpose if the peak voltages are ≤1 V.

- **Peak envelope analyzers** are designed to detect the envelope power. This is not possible with a simple diode sensor because the electronic setup of the diode must be different.

- **Feedthrough power sensors** are used to measure microwave power in transmission configuration. They have minor losses of approximately 0.5 dB and a limited bandwidth of typically 0.1 GHz to 1 GHz. The limiting device in these systems is a directional coupler with power splitters. Such a measurement can also be implemented with discrete elements. The characteristic figure of merit of these devices is the directivity ($a_D$), relating the read incident power $P_i$ to the read reflected power $P_r$ in case of reflection free load ($\Gamma_r = 0$):

$$a_D = 10\log\frac{P_r}{P_i} \text{ [dB]}$$

(55.8)

The directivity should be as high as possible.
The above power sensors are discrete devices. The maturity in microwave monolithic integrated circuit (MMIC) design and fabrication allows the integrated realization of diode power sensors; for example, in an integrated six-port reflectometer [12]. Activities to fabricate thermal power sensors integrable to MMIC-typical processes [13] can presently be implemented on commercial processes, such as the Philips Lemeill HEMT processes with additional postmicromachining [14].

**Commercially Available Power Measurement Systems**

A collection of different power sensors and corresponding measurement units is shown in Table 55.1. All power meters have GPIB interfaces for easy use in automated measurement.

### 55.2 Frequency Measurement

Frequency measurement in the microwave regime is usually part of a more complex measurement procedure, for example, determining the scattering parameters and filter characteristics of a DUT. If one is only interested in frequency or a higher accuracy is required, one must use direct frequency measurement systems.

Two different techniques can be distinguished. The rather old-fashioned way is to use mechanically tunable resonators, the so-called wave meters. These are not explained in detail here. Digital frequency counters are an alternative and are now the state of the art (Table 55.2).

The digital frequency counter measurement system is based on the principle of counting the zero crossovers of a continuous sinusoidal signal. At low frequencies, this method can be used directly; whereas in the microwave region, direct digital counters are not available because of their limited bandwidth. Thus, a modified measurement system must be used.

The standard digital frequency counter usually consists of a mixer, a local oscillator (frequency \( f_0 \)) in the lower frequency regime, several multipliers, and the digital counter. The principal measurement technique is shown in Figure 55.4.

An extremely stable local oscillator (quartz oscillator) is used to provide the reference signal used in the measurement system. This signal is multiplied by a factor of \( N \) and mixed with the RF signal of the DUT. The IF in the low-frequency range can be easily counted and, thus, the frequency of the signal \( f_s \) can be calculated according to the following equation.

\[
  f_s = f_0 + Nf_0
\]  

(55.9)

For this method, an extremely stable low-frequency oscillator (often temperature controlled) must be provided and, in order to allow a sufficient bandwidth, a high number of multipliers must be implemented in this system.

A pulsed oscillator with extremely short risetime can circumvent this problem. In the frequency domain, this signal is given by spectral lines at \( f = nf_0 \), where \( f_0 \) denotes the fundamental frequency of the pulses. Using a bandpass filter, a single frequency can be separated and transferred to the mixer.

### 55.3 Spectrum Analysis

The expression spectrum analysis subsumes the measurements that are performed to obtain the Fourier transformation \( S(f) \) of a given signal \( s(t) \). The Fourier transformation of \( s(t) \) in the frequency domain is defined by the equation:

\[
  S(f) = \int_{-\infty}^{\infty} s(t)e^{-j2\pi ft} dt
\]  

(55.10)

In practice, the lower and upper bounds of the integral are limited by a finite measurement time that must be fixed by the user.

For the analysis of an unknown spectrum, different methods can be distinguished:

- **Wave analyzers and selective voltmeters**: These devices utilize a tunable filter for frequency-selective measurements.
- **Spectrum analyzers** rely on the principle of heterodyne mixing with subsequent bandpass filtering.
- Calculation of the spectrum using a **fast Fourier transformation** (FFT). This method can be employed only for lower frequencies, since a digital-to-analog converter is needed. For microwave frequencies, the calculation of the spectrum using the FFT is, therefore, difficult to realize.

Since the spectrum analyzer is most suitable for microwave frequencies, it will be described in detail in the following. Brief introductions into the spectrum analyzer measurement techniques are given in [15, 16].

**Spectrum Analyzer**

The spectrum analyzer is most suitable for the analysis of microwave signals. It is a general-purpose instrument for measurements in the frequency domain and provides the user with the amplitude, power, or noise density of a signal depicted vs. the frequency. The frequency scale is in most cases linear; the vertical axes can be either linear or logarithmic. Spectrum analyzers are available from a few hertz up to more than 100 GHz. They give a quick overview of the spectral power distribution of a signal. Spectrum analyzers have a large dynamic range, a resolution bandwidth of a few hertz, and a reasonable frequency resolution.

**FIGURE 55.4** Block diagram of a digital frequency counter.
The spectrum analyzer is suitable for the following measurements:

- **Measurement of absolute and relative frequency**: Frequency drift (unstabilized oscillators), spectral purity, and frequency of harmonics.
- **Absolute and relative amplitude**: Gain of frequency multipliers, harmonics of periodic signals, intermodulation (IM) distortion, and harmonic distortion.
- **Scalar network analysis (if equipped with a tracking generator)**: Frequency response of amplifiers and filters.
- **Electromagnetic interference (EMI) measurements**: Broadband spectra.
- **Measurements of modulated signals**: AM, FM, or PM.
- **Noise**: Many spectrum analyzers can be used for noise measurements of active devices.
- **Phase noise**: Phase noise of oscillators can be analyzed with spectrum analyzers [17].

**Spectrum Analyzer Setup**

The spectrum analyzer is basically an electronically tunable filter that allows the measurement of the amplitude, power or noise at a certain frequency. Using the example shown in Figure 55.5, the principle of operation can be explained as follows.

The tunable filter used to separate the frequencies to be measured is realized using a chain of mixers and IF amplifiers. In this case, three mixers convert a given input signal frequency $f_s$ to the IF passband of the last IF amplifier. At least one of the oscillators is tunable (VCO) in order to scan the input frequency $f_s$. Sometimes, more than one tunable oscillator is used.

The first mixer and the following IF amplifier with a bandpass center frequency of 1.95 GHz in the given example selects the input frequency to be analyzed according to:

$$f_s = f_{i1} - 1.95 \text{ GHz}$$  \hspace{1cm} (55.11)

The input frequency for the spectrum analyzer shown in Figure 55.4 can be due to the scan of the frequency of the tunable oscillator $f_{i1}$ between 50 MHz and 2.05 GHz. However, the image frequency $f_i$ will also be mixed to the IF:

$$f_i = f_{i1} + 1.95 \text{ GHz}$$  \hspace{1cm} (55.12)

Since $f_i$ is in the range of 3.95 GHz to 5.95 GHz, a bandpass filter with a cut-off frequency of 3 GHz is used at the input to reject the image frequency.
Because it is difficult to realize a narrow bandpass at 1.95 GHz, the signal is converted to a lower frequency in the megahertz range. At these frequencies, stable quartz filters with high quality factors can be employed. In principle, the RF frequency could be mixed down to the last IF section in one step. However, in such an arrangement, it would be difficult to suppress the image frequencies. In any case, the image frequency of each stage should be rejected by the preceding IF amplifier as shown in Figure 55.6 for the second stage of the given example.

The last IF amplifier is very important for the performance of the complete system. In nearly all spectrum analyzers, its bandwidth — the so-called resolution bandwidth — can be adjusted in steps. For separation of closely spaced spectral components, the bandwidth should be very small. Most spectrum analyzers offer a minimum bandwidth of a few hertz. On the other hand, larger bandwidths are needed, since for a narrow IF filter only a slow scan speed can be allowed (see below) and, therefore, the measurement over several frequency decades would result in a large sweep time. The shape of the IF filter is important for the capability of the spectrum analyzer to separate close spectral components. The performance of the IF filter is described by the shape factor. It is defined by the ratio of the 60 dB to the 3 dB bandwidth of the IF filter. The IF filter can be switched between linear and logarithmic amplification.

A sawtooth generator produces the control voltage for the voltage-controlled oscillator (VCO) and the x-deflection voltage of the screen. A significant error is introduced in the frequency scale by a non-ideal voltage-to-frequency characteristic of the VCO. Therefore, in many cases, synthesizers with a quartz-stabilized phase-locked loop [18] are used.

The detector has to be sensitive either to the amplitude, the power, or the noise (mV $\sqrt{\text{Hz}}$). In modern spectrum analyzers, digital signal processing is used for this purpose.

It is important to note that there are restrictions on the minimum sweep time $T_s$. In order to avoid settling errors of the narrow band pass IF amplifier with bandwidth $B$, the scan time should be for a frequency span $S$ larger than [19, 20]:

$$T_s > 20S/B^2$$  \hspace{1cm} (55.13)

Most of the spectrum analyzers control the scan time automatically according to this equation.
Harmonic Mixing

For higher frequencies, the harmonic mixing technique is widely used. If the first 3-GHz low-pass filter in Figure 55.5 is omitted and the VCO produces harmonics, a larger number of input frequencies are converted to the passband of the spectrum analyzer. For the example shown, the possible input signals are depicted in Figure 55.7 vs. the VCO frequency according to:

\[ f_s = n f_{01} \pm 1.95 \text{GHz} \]  

(55.14)

The notation of the numbers in the figure are the harmonic number \( n \) and the plus or the minus sign in the above equation. For a frequency \( f_{01} = 3 \text{GHz} \) of the VCO, the following frequencies will appear at the same frequency location on the screen: 1.05 GHz (1–), 4.95 GHz (1+), 4.05 GHz (2–), 7.95 GHz (2+), 7.05 GHz (3–), 10.95 GHz (3+). A tracking preselection filter (see below), which is scanned with the VCO, can select one of these harmonics.

For further extension of the frequency in the upper mm-wave range, external mixers are used. With such an arrangement, frequencies higher than 500 GHz can be measured. Additionally, equipment for mixing of signals in the optical range is offered by some companies.

Tracking Preselection

For small input signals, the spectrum analyzer can be considered a linear device. However, if the input level increases, harmonics and intermodulation products are generated due to the nonlinearities of a mixer. These products result in spurious signals on the screen of the spectrum analyzer. In addition, image frequencies will appear on the screen, as demonstrated above. To avoid these spurious responses, a tracking preselection filter is employed at the input of the spectrum analyzer. A tracking preselection filter is an electronically tuned bandpass filter usually realized using a YIG filter.
Tracking Generator

Spectrum analyzers are often equipped with a tracking generator. The principle is shown in Figure 55.8. A local oscillator, with a frequency exactly on the center frequency of the IF amplifier is mixed by an identical setup as in the analyzer path. Using the same local oscillator as in the analyzer path ensures that the frequency of the tracking generator follows precisely the center frequency of the swept window of the analyzed frequency band.

The tracking generator can be used for network analysis. If the tracking frequency is used as an input signal of a two-port, the amplitude of the output can be measured with the spectrum analyzer. Such a network analyzer has the advantage of being sensitive only in a very narrow band. Thus, third-order intermodulation products and noise are suppressed. However, only scalar measurements can be performed.

Commercially Available Spectrum Analyzers

A number of commercially available, general-purpose spectrum analyzers for the microwave and mm-wave range are listed in Table 55.3. Only a small number of spectrum analyzers available on the market are presented. Most of the companies offer special equipment for production quality control. These spectrum analyzers can be computer controlled for fixed measurement routines. On request, spectrum analyzers with special options like fixed frequency operation, multichannel operation, support of external mixers, integrated frequency counters, and digital storage are available.

Typical specifications of microwave spectrum analyzers include:

- The frequency span is several gigahertz.
- With external mixers, the upper frequency limit can be extended to more than 100 GHz.
- The frequency accuracy is between $10^{-5}$ and $10^{-7}$. 

---

FIGURE 55.8 Principle of a tracking generator, which delivers at the port $RF_{\text{out}}$ a signal that is precisely in the passband of the spectrum analyzer.
The resolution bandwidth (i.e., the effective bandwidth of the narrow IF filter) can be adjusted in steps between 1 Hz and a few megahertz.

- The resolution bandwidth shape factor is typically 10:1.
- The amplitude accuracy is about 1 dB.
- The noise floor is at about –140 dBm.

### 55.4 Cavity Modes and Cavity Q

Cavities are used in a variety of applications. For example, they can be used to construct filters and they serve as those elements in microwave generators (e.g., klystrons) that determine the operating frequency. Cavities can also be applied in order to measure the frequency or the wavelength of microwaves (wave-meter). The most important parameters of a cavity are its resonant frequency and its q-factor. The latter determines the sharpness of the resonance, or, in case of filters, the bandwidth of the passband.

A cavity can be defined as a volume that is almost completely surrounded by a metallic surface. At one or two positions, coupling elements are applied to the metal surface in order to connect the cavity to other circuit elements. In the case of one coupling element, one speaks of a single-ended cavity; whereas a transmission cavity has two coupling elements. The coupling elements are usually small compared to the dimensions of the cavity. The inside of the cavity is filled with dielectric material (e.g., air: $\varepsilon_r = 1$).

Cavities are used as resonators for microwave applications. Therefore, they are comparable to low-frequency resonant circuits consisting of an inductance $L$ and a capacitance $C$. In the low-frequency range, lumped elements (inductors and capacitors) are used, which are small in comparison with the wavelength. In contrast, cavities are distributed elements with dimensions comparable to the wavelength. This results in comparatively small losses. Since cavities are distributed elements, it is in general no longer

</tbody>
</table>
possible to determine \( L \) and \( C \) directly. Instead of \( L \) and \( C \), the resonant frequency \( f_0 = \omega_0 / 2\pi \) is the most important property of a cavity.

Neither lumped elements nor cavities are completely lossless. One must take into account the finite conductivities of the materials, resulting in a resistance \( R \) when analyzing resonant circuits. For cavities, however, \( R \) cannot be determined directly due to the same reasons that hold for \( L \) and \( C \). Therefore, a different parameter, the q-factor \( Q \) plays a similar role for cavities. \( Q \) is proportional to the stored electric and magnetic energy \( W \), divided by the power loss \( P \):

\[
Q = \frac{\omega_0 W}{P} \tag{55.15}
\]

Although cavities are distributed elements, one is able to show that their behavior near resonance can be described by a simple parallel resonant circuit consisting of \( R, L, \) and \( C \) if the reference plane is chosen appropriately. Therefore, the basic properties of such a parallel resonant circuit are analyzed in the following.

Assume that the losses are small (\( Q \gg 1 \)), which is desirable in practice. Therefore, the resistance \( R \) of the parallel resonant circuit is comparatively large. In this case, the resonant frequency does not depend on \( R \) in a first-order approximation:

\[
\omega_n = \frac{1}{\sqrt{LC}} \tag{55.16}
\]

In Equation 55.15 is applied to the analyzed parallel resonant circuit, one obtains:

\[
Q = \frac{R}{\omega_0 L} = R \frac{\sqrt{C}}{L} \tag{55.17}
\]

One can characterize the width of a resonance curve by those angular frequencies \( \omega_1 = 2\pi f_1 \) and \( \omega_2 = 2\pi f_2 \) where the power has decreased to one-half of its maximum value (-3 dB). The impedance has then decreased to \( 1/\sqrt{2} \approx 70.7\% \) of its maximum value. This enables calculation of the angular frequencies \( \omega_1 \) and \( \omega_2 \):

\[
\omega_1 = \omega_0 - \frac{1}{2RC}, \quad \omega_2 = \omega_0 + \frac{1}{2RC} \tag{55.18}
\]

Using these relations, one can easily derive the following equation, which is equivalent to Equation 55.17.

\[
Q = \frac{\omega_0}{\omega_2 - \omega_1} = \frac{f_0}{f_2 - f_1} \tag{55.19}
\]

This expression shows that \( Q \) is a symbol for the sharpness of resonance. Furthermore, it leads to the first principle as to how the q-factor can be measured. This principle, which is often referred to as the bandpass method, is based on the measurement of a resonance curve. For example, one can measure the reflection coefficient \( S_{11} \) with a network analyzer. From this curve, the 3 dB-bandwidth \( Af = f_2 - f_1 \) and the resonant frequency \( f_0 = (f_1 + f_2)/2 \) can be easily determined. The application of Equation 55.19 yields the desired \( Q \).

A second principle used to measure the q-factor is based on the transient behavior of the cavity after excitation with a pulse. In this case, the energy decays exponentially, and the time constant of the decay is proportional to \( Q^{-1} \). This can again be shown by analyzing the equivalent parallel resonant circuit. Up
until now, all signals were time-harmonic, which enabled a solution by complex quantities. This time, the corresponding differential equation must be solved. One can easily show that the amplitude of the voltage is proportional to \( e^{-\omega_0 t/2Q} \), which means a \( e^{-\omega_0 t/2Q} \) dependency of the energy exists. Measuring the decay time constant, therefore, enables one to determine the q-factor.

The \( Q \), defined here is the unloaded \( Q \) of the cavity; that is, no further resistance is connected to the cavity. Sometimes it is desirable to determine the loaded \( Q \) (\( Q_L \)), which takes into account such resistances. Detailed information about the loaded \( Q \) can be found in [21–23]. Although the q-factor is not influenced by the coupling structure if it is lossless, the coupling structure is of great importance. Further information about coupling parameters is presented in [21–23]. Detailed descriptions of measurement methods based on the above mentioned principles can also be found in [21, 22].

Up to now, all analyses were based on the equivalent resonant circuit. There are many other effects that can be explained by this analogy. For example, the energy in both the cavity and in its equivalent circuit oscillates between the magnetic and electric fields. Some properties of cavities, however, can only be seen by examining the electric and magnetic fields themselves. These are governed by Maxwell’s equations.

A solution of Maxwell’s equations (which can be very complicated for a given cavity) shows that all cavities have an infinite number of resonant frequencies. This could not be seen by analyzing the equivalent parallel resonant circuit. A description of the cavity by a discrete parallel resonant circuit is only valid in the vicinity of one of these resonant frequencies.

Furthermore, different modes can exist that have the same resonant frequency. This phenomenon is called degeneration. If the resonator will operate at such a frequency, where degenerate modes exist, one has to take care that the companion mode is suppressed. This can be accomplished by an appropriate choice of the positions of the coupling elements.

Even if the desired mode does not have any companion mode, one should take care that no other mode exists in the operating range of the cavity (this can be accomplished with a mode chart [22, 23]); otherwise, these modes must be damped sufficiently in order to be sure that an observed resonance corresponds to the desired mode.

### 55.5 Scattering Parameter Measurements

Scattering parameters describe multiple port structures in terms of wave variables. The introduction of scattering parameters (S-parameters) arises naturally in microwave circuits and systems, due to the lack of a unique definition for currents and voltages at these frequencies. Most circuits and systems at high frequencies are efficiently described in terms of S-parameters.

This section describes the fundamentals and properties of S-parameters, together with network analysis based on S-parameter calculations and measurements. Measurement procedures are outlined and the most frequently used systems for S-parameter measurement are described. Finally, information on hardware required for the experimental determination of S-parameters is provided, together with the corresponding suppliers.

**Introduction and Fundamentals**

At high frequencies, the wave variables are a natural extension of the voltages and currents at port terminals. In electric systems where the voltages and currents cannot be uniquely defined, the power flow in a waveguide can be described via wave variables. Whenever a TEM mode of wave propagation cannot be assumed, the currents and voltages are dependent on the integration path. This situation is encountered in all rectangular, circular, and passive waveguide structures, even in the case of lossless wave propagation. It is also true for all guiding structures if losses are to be considered along the path of wave propagation [24–27]. For the case of wave propagation along a transmission line, the wave variables \( a \) and \( b \) are defined as follows:
The propagation is along the \( z \)-direction. The characteristic impedance of the transmission line is \( Z_0 \), and \( U(z) \) and \( I(z) \) are the voltage and current, respectively at location \( z \) along the line. The variables \( a(z) \) and \( b(z) \) are the complex amplitudes of the modes on the line. The voltage \( U^+ \) and \( U^- \) and the currents \( I^+ \) and \( I^- \) denote the voltage and current amplitudes, respectively, in forward and reverse direction. The wave variables are related to the power in the following form:

\[
\begin{align*}
\alpha(z) &= \frac{1}{2} \left( \frac{U(z)}{\sqrt{Z_0}} + I(z) \sqrt{Z_0} \right) \\
&= \frac{U_+}{\sqrt{Z_0}} = I_+ \sqrt{Z_0} \\
\beta(z) &= \frac{1}{2} \left( \frac{U(z)}{\sqrt{Z_0}} - I(z) \sqrt{Z_0} \right) \\
&= \frac{U_-}{\sqrt{Z_0}} = I_- \sqrt{Z_0}
\end{align*}
\]

(55.20)

In Equation 55.21, it is assumed that the system is excited by a pure sinusoid and that the characteristic impedance is purely real. The wave variables have the dimensions of \( \sqrt{W} \).

Strictly speaking, wave variables and S-parameters can only be applied to linear networks. This is important because many publications are devoted to so-called large-signal S-parameter measurements. The interpretation of such results is not simple and great care must be employed in the correct determination of the characteristic impedance of the system [26]. In the case of analysis of large-signal or nonlinear circuits, two methods exist to introduce the wave variables:

- Volterra series representation [28]
- Harmonic-balance method [26]

Both methods transform the nonlinear circuit into a number of linear circuits at different frequencies, and then change the terminal voltages and currents into wave variables. This situation is sketched in Figure 55.9. Particular attention must be paid to the definition of the characteristic impedance, which can vary between different frequencies. An in-depth treatment of wave variables can be found in [26].

A further utilization of wave variables can be found in the noise analysis of microwave circuits. According to Figure 55.10, a noisy multiport can be analyzed by an associated noiseless two-port with the according noise sources \( \xi \) at the corresponding ports of the circuit.

**Calculations and Analysis with S-Parameters**

The characterization of multiports with S-parameters requires embedding of the multiport into a system consisting of a signal source with a characteristic impedance and appropriate terminations of all ports.
This situation is shown in Figure 55.11. The outgoing wave parameters $b$ are reflections at the corresponding ports. The wave variables are related to the scattering parameters of a two-port in the following manner:

$$\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} = S \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} = \begin{pmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{pmatrix} \begin{pmatrix} a_1 \\ a_2 \end{pmatrix}$$

(55.22)

For the determination of the individual scattering matrix elements, all ports of the network must be terminated in their characteristic impedance. The impedances at the corresponding ports need not be equal for all ports. The $S$-parameters are, in general, complex and are defined with respect to reference planes. These reference planes can be the network terminals, but could also be shifted to other locations in the circuit if this is desirable. The scattering matrix can be transformed into all circuit representations. Table 55.4 indicates the conversion formulae between the $S$-parameters and $ZYh$ parameters for arbitrary characteristic impedances. Additional conversions to $ABCD$ and $T$ parameters can be found in [29].
The scattering parameters in the case of a noisy two-port as indicated schematically in Figure 55.10 are defined as [26]:

\[
\begin{pmatrix}
  b_1 \\
  b_2
\end{pmatrix} =
\begin{pmatrix}
  S_{11} & S_{12} \\
  S_{21} & S_{22}
\end{pmatrix}
\begin{pmatrix}
  a_1 \\
  a_2
\end{pmatrix}
+ \begin{pmatrix}
  c_1 \\
  c_2
\end{pmatrix}
\]

(55.23)

The noise wave sources \( c_1 \) and \( c_2 \) represent the noise generated in the circuit and are therefore complex variables varying with time. They are characterized by a correlation matrix \( C_c \) as follows:

\[
C_c = \begin{pmatrix}
  c_1^* c_1 & c_1^* c_2 \\
  c_2^* c_1 & c_2^* c_2
\end{pmatrix} = \begin{pmatrix}
  |c_1|^2 & \Re(c_1 c_2^*) \\
  \Re(c_1 c_2^*) & |c_2|^2
\end{pmatrix}
\]

(55.24)

where the bar indicates times averaging, \((\cdot)^H\) denotes the Hermitian conjugate, and \(^*\) stands for the complex conjugate.

For the calculation of the cascade connection of two networks, it is desirable to convert the S-parameters to T parameters defined in the following way:

\[
\begin{pmatrix}
  b_1 \\
  a_2
\end{pmatrix} =
\begin{pmatrix}
  T_{11} & T_{12} \\
  T_{21} & T_{22}
\end{pmatrix}
\begin{pmatrix}
  a_1 \\
  b_2
\end{pmatrix}
\]

(55.25)

The conversion between S-parameters and T parameters is given below.

\[
T_{11} = S_{11} - \frac{S_{12} S_{22}}{S_{21}}
\]

(55.26)

\[
T_{12} = \frac{S_{11}}{S_{21}}
\]

(55.27)

\[
T_{21} = -\frac{S_{22}}{S_{21}}
\]

(55.28)

It should be emphasized that different definitions of the \( T \) parameters exist in the literature \([2, 24–27, 30]\). Power gain, mismatch, insertion loss, etc. can be efficiently described with the help of scattering parameters \([2, 30]\).

**Measurement of S-Parameters**

Network analyzers are generally used for the measurement of S-parameters. A schematic configuration of a network analyzer is indicated in Figure 55.12. The network analyzer consists of two structures to separate the signals and a heterodyne receiver. According to the definitions, the measurement is performed in two steps as indicated in Figure 55.13. Different error models are employed for the calibration of the network analyzer. The most simple is the one-port error model, which consists of contributions due to directivity, source mismatch, and frequency response. A flow diagram is illustrated in Figure 55.14.

For the characterization of active and passive two-ports, a more sophisticated error model is required. The signal flow graphs of the full two-port model is drawn in Figure 55.15. To determine the S-parameters of the device under test, a de-embedding procedure is required \([31–43]\). The two-port error model is then divided into two error adapters and the actual device under test (DUT), as depicted in Figure 55.16. The example shown makes reference to the so called “TRL” calibration procedure. This name abbreviates the three calibration standards utilized in this method: a through standard with zero length, a reflecting standard, and a line standard. This method cannot be applied to on-wafer measurements at low frequencies, due to the excessive line length required for a broadband measurement. Other error correction methods are summarized in Table 55.5 \([44]\). In addition to the measurements given in the table, a known reference impedance and port 1 to port 2 connection are required. Furthermore, at higher frequencies (above \( \approx 15 \) GHz), a calibration measurement of the isolation should be performed. For this purpose, both ports are terminated by their characteristic impedances and a transmission measurement is performed. This measurement determines the values of \( C_F \) and \( C_R \) in the calibration flow diagram (see Figure 55.14).
FIGURE 55.13 Flow diagram of the measurement procedure.

\[
S_{11M} = E_D + E_{RT} \frac{S_{11A}}{1 - E_S S_{11A}}
\]

FIGURE 55.14 Flow diagram of the two-port error model.

\[ E_{RT} = \text{Reflection tracking} \]
\[ E_S = \text{Source Match} \]
\[ S_{11M} = \text{Measured} \]
\[ S_{11A} = \text{Actual} \]
Another possibility for performing vector network measurement is based on multiport reflectometers [45]. The advantage of such systems is the reduced complexity of the network analyzer receiver. A possible realization of a reflectometer structure is the so-called six-port reflectometer. The reflectometer consists of three couplers and four power sensors. No frequency conversion is required, which simplifies the test equipment.

Introduction

Photoconduction has been observed, studied, and applied for more than 100 years. In the year 1873, W. Smith [1] noticed that the resistance of a selenium resistor depended on illumination by light. Since that time, photoconduction has been an important tool used to evaluate materials properties, to study semiconductor device characteristics, and to convert optical into electric signals. The Radio Corporation of America (RCA) was a leader in the study and development of photoconductivity and of photoconductive devices. Richard H. Bube of RCA Laboratories wrote the classic book *Photoconductivity in Solids* [2] in 1960. Today, photoconducting devices are used to generate very fast electric pulses using laser pulses with subpicosecond rise and fall times [3]. For optoelectronic communications, photoconducting devices, allow operation in the gigabit per second range.

Photoconductive devices normally have two terminals. Illumination of a photoconductive device changes its resistance. Conventional techniques are used to measure the resistance of the photoconductor. Frequently, small changes in conductivity need to be observed in the study of material or device characteristics. Also, in the measurement of light intensities of faint objects, one encounters small photoconductive signals.
Only solid photoconductors, such as Si, PbS, PbSe, and HgCdTe, will be treated here. Photoconduction has been observed in amorphous, polycrystalline, and single-crystalline materials. During the last decade, major improvements in materials growth have occurred which directly translate in better device performance such as sensitivity and stability. Growth techniques such as molecular beam epitaxy (MBE) and metal organic chemical vapor deposition (MOCVD) allow the growth of single-crystal layers with an accuracy of the lattice constant. Artificially structured materials can be fabricated with these growth techniques for use in novel photoconducting devices.

Absorption of light in semiconductors can free charge carriers that contribute to the conduction process. Figure 56.1 presents the band diagram for a direct bandgap semiconductor where the excitation processes are indicated. Excitation process (a) is a band-to-band transition. The photon energy for this excitation has to exceed the bandgap of the semiconductor. The absorption constant is larger for this process than for any of the other processes shown in this figure. Typical semiconductors used for electronic applications have bandgaps in excess of 1 eV, corresponding to light in the near-infrared region. Special semiconductors have been developed with narrower bandgaps to provide absorption in the mid- and long-wavelength infrared regions. Indium antimonide (InSb) and mercury-cadmium-telluride (HgCdTe) semiconductors provide photosensitivity in the 4- and 10-μm wavelength range, respectively. The photogenerated carriers increase the electron and hole densities in the conduction and valence bands, respectively, which leads to an increase in conductivity [4]. For the simplified case with one type of carrier dominating, the conductivity \( \sigma \) is given by:

\[
\sigma = ne\mu
\]  

(56.1)

where \( n \) is the density of free carriers, \( e \) their charge and \( \mu \) their mobility. Absorption of light results in a change in free carrier density and a corresponding change in conductivity \( \Delta \sigma \):

\[
\Delta \sigma = \Delta ne\mu + \Delta \mu en
\]  

(56.2)

**FIGURE 56.1** Example of electronic transitions in a photoconductor: (a) band-to-band excitation, (b) excitation from a trap or a donor, and (c) transition from a trap or an acceptor to the valance band; \( h\nu \) is the energy of the absorbed photon.
Δσ is the definition for photoconductivity. In Eq. 56.2, one assumes that due to the photon absorption the density of carriers changes. Also, the mobility of the carriers changes due to the modified free carrier density. The latter effect is very small except for special band transitions, as with InSb at very low temperatures.

Figure 56.1 indicates that other excitation processes exist. For example, bound electrons can be excited into the conduction band. This process can lead to persistent photoconductivity. In this example, the trapped holes have a long lifetime while the electrons move freely due to the applied electric field. Charge neutrality requires that the electrons collected at the anode be replenished by electrons supplied by the cathode. This effect leads to an amplification of the photogenerated charge (i.e., more than one electron is collected at the anode of the photoconducting device per absorbed photon). Often, the storage times are long, in the millisecond range. Hence, photoconductive devices with large amplification have a slow signal response.

Small bandgap semiconductors, such as HgCdTe and InSb, are difficult to manufacture. Thus, artificially structured layers of commonly used materials are being developed to replace these. Spatial modulation of doping has been proposed by Esaki and Tsu [5] to achieve a lattice containing a superlattice of n-doped, undoped, p-doped, and undoped layers (n-I-p-I). Due to the energy configuration of this structure, the effective bandgap is less than that of the undoped material. The effective bandgap depends on the thickness of the layers and their doping concentrations. The quantum-well infrared photodetector (QWIP) [6] is another approach to obtain photoconduction in the far-infrared wavelength range. In this structure, energy wells exist in the conduction band of the material heterostructure due to the energy band discontinuities. Subbands form in the superlattice and electrons in these wells are confined due to

![Figure 56.2a](image-url)
Infrared photons can excite electrons from their confined states to the continuum, which leads to an increase in conductivity.

While it is possible to use noncontact methods to measure the conductivity in a material, electric contacts are commonly placed onto the structure during the device fabrication process. Typically, ohmic contacts are formed to fabricate metal-semiconductor-metal (MSM) structures (Figure 56.2). These contacts control the Fermi level in the material structure and provide carriers to retain charge neutrality.

### Detector Performance Parameters

#### Responsivity

Variations in photon flux density incident on a photoconductor interact with the material to change the conductivity. These changes produce a signal voltage that is proportional to the input photon flux density. The detector area $A$ collects flux contributing to the signal. $I_s$ is the integrated power density over a spectral interval. Responsivity ($R_v$) is the ratio of the rms signal voltage (or current) to the rms signal power and is expressed in units of volts per watt. It is expressed as amps per watt for current responsivity.

$$ R_v = \frac{V}{A J_s} $$

$V_s$ is normally linear with photon flux for low levels, but can saturate under high flux conditions. One should ensure operation in the linear range for radiometric and photometric instrumentation.

#### Noise

The performance of a visible or IR instrument is ultimately limited when the signal-to-noise ratio equals one (SNR = 1). The noise from the instrument’s signal processing should be less than the noise from the
detector in the ideal case. This means reducing this noise within the restrictions of signal processing design limitations. These may include cost, size, and input power. The detector noise should be minimized.

Johnson noise is the limiting noise in all conductors [7]. It is frequency independent, and independent of the current going through the device. Johnson noise is defined in Equation 56.4, where $k$ is the Boltzmann constant ($1.38 \times 10^{-23}$ J/K), $T$ is the detector temperature (K), $R$ is the resistance ($\Omega$), and $\Delta f$ is the amplifier bandwidth (Hz).

$$V_J = \sqrt{4kTR\Delta f}$$  \hspace{1cm} (56.4)

Another type of noise known as $1/f$ noise ($V_f$) is present in all semiconductor detectors that carry current. The spectrum of this noise varies as $1/f^n$, with $n$ approximately 0.5 [8].

Noise due to fluctuation in generation and recombination of charge carriers [9] varies linearly with current. This noise may be caused by the random arrival of photons from the background (photon noise), fluctuation in the density of charge carriers caused by lattice vibration ($g-r$ noise), by interaction with traps, or between bands.

Excess noise from the amplifier or signal processing ($V_{amp}$) can also limit photoconductive detector performance.

These uncorrelated noises add in quadrature, giving the total noise ($V_N$):

$$V_N^2 = V_J^2 + V_{g-r}^2 + V_{amp}^2$$  \hspace{1cm} (56.5)
The total noise may be given in units of $V\sqrt{Hz}$. It may also be integrated over some frequency range to provide volts rms. Photoconductive detectors often have a $g_r$ noise independent of frequency from dc to 100 kHz.

**Detector Sensitivity**

Minimum detectable signal power, that is, Noise Equivalent Power (NEP) is a convenient means to express detector sensitivity. NEP is expressed in units of watts or $W\sqrt{Hz}$.

\[
\text{NEP} = \frac{V_N}{R_V}
\]

(56.6)

The reciprocal of NEP, the detectivity $D$ is frequently used. In attempting to make possible comparison among detectors, detectivity can be normalized to an electronic bandwidth of 1 Hz and a detector area of 1 cm$^2$. This yields the highly used parameter specific detectivity or $D^*$ (pronounced “dee-star”) [10]:

\[
D^* = \frac{(R_V/V_N)\sqrt{(AAf)}}
\]

(56.7)

The units of $D^*$ are cm $\times$ Hz$^{1/2}$/W, sometime simplified to “Jones”.

This normalization is based on evidence that noise varies as the square root of the electronic bandwidth and $D$ varies inversely as the square root of the detector area. This relationship may not hold closely over a wide range of device sizes and bandwidths. Comparison of device performance is most meaningful among devices having similar sizes and measured under similar conditions, including operating temperature, chopping frequency/scanning rate, and detector field of view.

**Preparation and Performance of Photoconductive Detectors**

**Cadmium Sulfide**

CdS is normally prepared by vapor deposition or sintering a layer of high-purity CdS powder on a ceramic substrate [11]. It has the largest change in resistance with illumination of any photoconductor. The peak response of this intrinsic detector is at 0.5 $\mu$m. Its spectral response is similar to that of the human eye and operates without cooling.

**Lead Sulfide**

PbS was among the earliest IR detector material investigated. Cashman was one of the earliest researchers in the U.S. [12]. This intrinsic detector material is prepared by deposition of polycrystalline thin films by vacuum sublimation or chemical deposition from a solution. The spectral response extends to approximately 3 $\mu$m. PbS operates over the temperature range from 77 K to room temperature. The frequency response slows considerably at the lowest temperatures. The spectral response extends to somewhat longer wavelengths with cooling.

**Lead Selenide**

PbSe is an intrinsic detector that operates over the temperature range from 77 K to room temperature. Its spectral response extends to longer wavelengths with cooling. Preparation of PbSe is by sublimation or chemical deposition. Noise in PbSe detectors follows a 1/$f$ spectrum.

**Indium Antimonide**

InSb is prepared by melting together stoichiometric quantities of indium and antimony. It operates over the range from 77 K to room temperature. The higher performance and ease of operation with signal processing electronics lead photovoltaic InSb detectors to be much more widely used than photoconductive.

**Mercury Cadmium Telluride**

HgCdTe is a versatile intrinsic material for IR detectors. CdTe and HgTe are combined to form the alloy semiconductor Hg$_{1-x}$Cd$_x$Te. For the alloy with $x = 0.2$, the bandgap is approximately 0.1 eV, providing a
long wavelength cutoff of 12.4 μm. HgCdTe was initially grown into bulk crystals by solid-state crystallization (also called quench and anneal). Currently, thin film growth techniques of liquid phase epitaxy (LPE), MOCVD, and MBE are preferred to obtain larger, more uniform wafers. By appropriately choosing the alloy composition, photoconductive HgCdTe detectors are possible over the 2- to 20-μm range. CdZnTe wafers permit lattice-matched surfaces for HgCdTe thin film growth. Operating temperatures can range from 77K to room temperature, with the lower temperatures necessary for the longer wavelength devices.

Extrinsic Germanium and Silicon

The photoresponse of an extrinsic detector occurs when a photon interacts with an impurity added to a host semiconductor material. With an intrinsic material, the photoresponse is from the interaction with the basic material.

For the extrinsic detector, incident photons may produce free electron-bound hole pairs, or bound electron-free hole pairs. The extrinsic detector’s spectral response is achieved using an impurity (or doping element). Intrinsic detection occurs with a detector having the necessary bandgap width for the desired spectral response.

Extrinsic detectors require lower temperatures than do intrinsic and QWIPs, but have the advantage of longer wavelength response.

Ge and Si are zone refined to achieve high purity by making multiple passes of a narrow molten zone from one end to the other of an ingot of the material. Unwanted impurities can be reduced to levels of 10^{12} to 10^{13}/m^{3} [13]. Growth of single crystals is by the Czochralski approach of bringing an oriented seed crystal in contact with the melt and withdrawing it slowly while it is rotated, or by applying the horizontal zone refining approach, whereby an oriented seed crystal is melted onto the end of a polycrystalline ingot. A molten zone is started at the meeting of the ingot and seed and moved slowly down the ingot, growing it into a single crystal. An inert atmosphere is required to prevent oxidation.

Hg, Cd, Cu, and Zn are impurities for doping Ge detectors; Ga and As are dopants for Si detectors. See Table 56.1 and Figure 56.3.

From References 14 and 15.

Gallium Arsenide/Aluminum Gallium Arsenide QWIP

QWIP technology uses a quantum-well structure to provide intraband (intersubband) transitions to achieve an effective long-wavelength response in a wide bandgap material. Quantum wells are used to provide states within the conduction or valence bands. Since hν of the desired spectral region is less than the bandgap of the host material, the quantum wells must be doped. Quantum-well structures are...
designed to permit photoexcited carriers to depart the structure, and be accumulated as signal (photo-current). The QWIP detector is generally comparable to extrinsic photoconductive detectors [16], in that both have lower than desirable quantum efficiency. GaAs/AlGaAs QWIPs have the advantage of higher operating temperatures than extrinsic detectors.

Instrumentation

The Stanford Research Systems SR570 low-noise current preamplifier can be used to amplify the current flowing through a photoconductive device. This preamplifier can be programmed to apply a voltage to the terminals of the photoconducting device. Its output voltage is proportional to the device current. Frequently, the IR radiation or visible light is chopped and the ac component of the device current is detected using lock-in-amplifier techniques. This approach allows the study of very small changes in device conduction. The Stanford Research Systems SR570 and the EG&G Instruments Model 651 are examples of a lock-in amplifier and a mechanical radiation/light chopper, respectively.

### 56.2 Photojunction Sensors

*Michael R. Squillante and Kanai S. Shah*

**Introduction**

*Photojunction sensors* (photodiodes and phototransistors) are semiconductor devices that convert the electrons generated by the photoelectric effect into a detectable electronic signal. The *photoelectric effect* is a phenomenon in which photons lose energy to electrons in a material. In the case of a semiconductor, when the energy of an interacting photon ($h\nu$) exceeds the energy of the semiconductor bandgap ($E_g$), the energy absorbed can promote an electron from the valence band to the conduction band of the material. This causes the formation of an electron-hole pair. In the presence of an electric field, these charges drift toward electrodes on the surface and produce the signal.

The junction in the photojunction device creates a diode that provides a small built-in electric field to propel the charges to the electrodes (photovoltaic mode of operation). In the photovoltaic mode, either the photocurrent or the photovoltage can be measured. This mode of operation provides very high sensitivity because there is no net reverse leakage current, but relatively poor frequency response occurs because of high capacitance and low electric field.

Photodiode devices are most often operated with a bias voltage applied opposing the junction (*reversed bias*) to provide the electric field. The presence of the junction in a diode allows for the application of a relatively large bias to be applied while maintaining a relatively low reverse leakage current and thus relatively low noise. The result of an applied bias on a junction is the increase of the “depletion region,” which is the sensitive volume of the detector. Any charges that are generated within this volume are swept toward the electrodes by the field, adding to the reverse leakage current. The *total reverse current* is the sum of the *dark current*, which occurs due to thermal generation of charges in the depletion region, and the *photocurrent*, which is produced due to optical illumination. Thus, the lower the dark current, the higher the sensitivity of the detector to optical illumination.

In an ideal diode, all of the light incident on the photodiode surface is converted to electron-hole pairs and all of the charges drift to the electrodes and are collected. In a real device, there are reflection losses at the surface, additional light is lost in the electrode and/or front layers of the device, and not all of the charges are collected at the electrodes.

There are several fundamental types of junction photodiodes [1], as shown in *Figure 56.4*. A *Schottky barrier* diode is a device in which the junction is formed at the surface of the semiconductor by the
application of a metal electrode that has a work function that is different from the work function of the semiconductor; a heterojunction diode is a device in which two different semiconductor materials with differing work functions are joined; a homojunction diode is a device in which the junction is created at an interface in a single material and the difference in work function is created by doping the material n-type and p-type. Most photodiodes are homojunction devices made using silicon. Other, more complex types of photojunction devices, which are discussed below, include p-i-n photodiodes, avalanche photodiodes (APD), drift photodiodes, and phototransistors.

FIGURE 56.4 Schematic of photodiode device structures: (a) Schottky junction, (b) homojunction, (c) heterojunction, (d) p-i-n, (e) APD, (f) drift diode.
Photodiodes are typically characterized by several properties, including bandwidth, spectral response, operating bias, operating temperature, dark current, junction capacitance, noise equivalent power, and peak wavelength. Other specifications usually provided by manufacturers include size, packaging details, operating temperature range, capacitance, and price.

Photodiodes are used in numerous applications, including CD-ROM systems, television remote control systems, fax machines, copiers, optical scanners, fiber optic telecommunication repeaters, surveillance systems such as motion detectors, certain smoke detectors, light meters, and a wide variety of scientific instrumentation including spectrophotometers, scintillation detectors, optical trackers, laser range finders, LIDAR, LADAR, analytical instrumentation, optical thermometers, nephelometers, densitometers, ratiometers laser detectors, shaft encoders, and proximity sensors. Photodiode arrays are available for use as position-sensitive detectors that can either be used for imaging (such as in laser scanners, night vision equipment, spectrophotometers, and edge detection) or alignment systems. Medical imaging applications such as x-ray CT scanners also use large arrays of photodiodes.

A variety of materials are used in the fabrication of photodiodes, but most are fabricated using silicon. Other materials used include CdS, Se, GaAs, InGaAs, HgCdTe, and PbS. In addition, materials with unique properties can be used to solve very specific and unusual problems, including Ge, GaP, HgMnTe, InP, HgI2, and InI.

Photodiodes are an alternative to photomultiplier tubes in many applications. There are a variety of advantages to be gained—including higher quantum efficiency, tailored spectral response, increased ruggedness, reduced power requirements, reduced weight, compact size, elimination of warm-up period, reduced sensitivity to temperature and voltage fluctuations, and insensitivity to magnetic fields. In general, photodiodes are noisier and require more sophisticated readout electronics than photomultiplier tubes, especially at room temperature. Upon cooling, the noise in photodiodes can be reduced significantly due to reduction in dark current.

Figure 56.5(a) shows a simple circuit for operating a photodiode in the photovoltaic mode. In this mode, photocurrent is usually measured because the photocurrent is nearly proportional to the input signal. The output of the photodiodes is typically connected to the input of an op-amp current-to-voltage converter. Figure 56.5(b) shows a simple circuit for operating a photodiode under reverse bias.

Table 56.2 shows a few examples of available photodiodes. These are only a small fraction of the commercially available photodiodes and photodiode manufacturers. Lists of photodiode manufacturers are available [2,3].

![Figure 56.5](image-url)
A simplified version of the equivalent circuit for a photodiode is shown in Figure 56.6, where $C_j$ = junction capacitance, $I_d$ = dark current (current present with no incident photons), $I_j$ = reverse saturation current, $I_o$ = output current, $I_p$ = photocurrent current, $R_j$ = junction shunt resistance (or parallel resistance), $R_s$ = series resistance, $V_j$ = junction voltage, $V_o$ = output voltage.

The dark current from this structure is ideally given by:

$$I_d = I_j \{ \exp((qV_j/kT) - 1) \} \quad (56.8)$$

where $k$ = Boltzmann’s constant, $q$ = electronic charge, $T$ = absolute temperature.

Total current under illumination is given by:

$$I_o = I_d + I_p \quad (56.9)$$

**Quantum Efficiency**

The *quantum efficiency* of a photodiode is the ratio of the charge pairs generated to the incident photons:

\[
\eta = \frac{I_p}{q/(P_i/h\nu)} \tag{56.10}
\]

Where \( P_i \) = optical power incident on the photodiode, \( h\nu \) = energy of the photons.

The *responsivity*, \( R \) is the ratio of the photocurrent to the incident optical power in amps/watt:

\[
R = I_p/P_i = \eta h\nu \tag{56.11}
\]

The photocurrent is given by rearranging Equation 56.9:

\[
I_p = q\eta P_i/h\nu \tag{56.12}
\]

**Noise**

There are two main sources of noise when using a photodiode: shot noise in the diode and thermal noise. The *shot noise* is related to the dark current by the formula:

\[
I_s = (2qI_dB)^{1/2} \tag{56.13}
\]

where \( B = \) bandwidth.

Assuming the diode shunt resistance and the input resistance of the measuring circuit to be used to measure the output of the photodiode are high relative to the load resistance, the thermal noise is given by:

\[
I_t = (4kTB/R_L)^{1/2} \tag{56.14}
\]

where \( R_L = \) load resistance. The total noise current, \( I_{nt} \), is the sum of these currents in quadrature.

**I–V Characteristics of Photodiodes**

With no illumination, photodiodes have I–V curves equivalent standard diodes given by Equation 56.8. Illumination by light causes the current to increase. Figure 56.7 shows a family of I–V curves for a photodiode under illuminations with equally increasing increments of incident light intensity. As the illumination on the device increases, the curve shifts downward by the amount of current generated by the incident light. The lower right-hand quadrant represents the photovoltaic mode of operation. When a photovoltaic device is operated in "current mode" with low or no load resistance (as with an operational amplifier, as in Figure 56.5(a) above), the output is linear with incident light intensity. When operated in "voltage mode" with a high load resistance, there is an exponential relationship between the output and the incident illumination. The lower left-hand quadrant shows the reversed bias mode of operation. Again, in this mode the output is nearly linear with the incident intensity.

**Output Current Under Reverse Bias**

In a reverse bias p-n junction under bias, the depletion width (\( W \)) increases as a function of applied bias (\( V_b \)) until the device is fully depleted. The dark leakage current (\( I_d \)) under reverse bias conditions can arise from the generation-recombination effects (\( I_G \)) and from diffusion (\( I_D \)) as well as surface effects. In most cases, the diffusion current is significantly smaller than the generation-recombination component. Thus, it is possible to assume that \( I_d = I_G \).

The analytical expression for \( I_G \) is as follows:
\[ I_o = \frac{AWq\eta}{2\tau} \]  \hspace{1cm} (56.15) 

where: \( A \) = device area, \( \eta \) = intrinsic carrier concentration, \( \tau \) = minority carrier lifetime.

The total diode current under illumination \( (I_o) \) is the sum of the dark leakage current \( (I_d) \) and the photocurrent \( (I_P) \):

\[ I_o = I_d + I_P \]  \hspace{1cm} (56.16)

**Position Sensitive Photodiode Arrays**

Many manufacturers offer photodiodes fabricated in a *quadrant* geometry. Four photodiodes are fabricated in a square, \( 2 \times 2 \) geometry. When coupled to a lens or a pinhole, they can be operated as position sensitive detectors. In operation, the outputs of the four photodiodes are monitored and the position of the light source can be determined by the projection of the light spot on the detector surface. More recently, manufacturers are offering linear and area arrays of photodiodes that can be used as imaging devices.

**Phototransistors**

Phototransistors are photojunction devices similar to transistors except that the signal amplified is the charge pairs generated by the optical input. Like transistors, phototransistors can have high gain. Phototransistors can be made on silicon using \( p \)- and \( n \)-type junctions or can be heterostructures. Figure 56.8 shows a sketch of the structure of a simple bipolar phototransistor, which is essentially the same as that of a simple bipolar transistor. The main difference is the larger base-collector junction, which is the light-sensitive region. This results in a larger junction capacitance and, although the devices have gain, the capacitance gives phototransistors lower frequency response than photodiodes.
Using thin film transistor (TFT) technology developed for flat panel displays, large arrays of phototransistors can be fabricated on amorphous silicon to form imaging devices that can be used in place of other imaging technologies such as vidicon tubes or even film. Examples of this are the very large area detectors (hundreds of square centimeters) being investigated for use in medical radiography by combining the TFT arrays with radiographic phosphor screens [4] or coupled to semiconductor films [5].

**Novel Silicon Photojunction Detector Structures**

**Silicon p-i-n Detectors**

Silicon p-i-n diodes are an extension of the standard p-n junction diodes, but are more attractive for low-noise applications due to reduced capacitance in these devices [1]. The reduction in capacitance is achieved by incorporating an intrinsic region between the p and n regions. This increases the depletion width of the detector and thereby lowers its capacitance. Silicon p-i-n detectors can be designed to have higher frequency response than p-n junctions and therefore are more popular.

In operation, p-i-n detectors are similar to p-n junction detectors, but the surface region (either p or n) is made thin so that the optical photons penetrate this entrance layer and are stopped in the intrinsic (i-region) where electron-hole pairs are produced, as shown in Figure 56.4. These electron-hole pairs are swept toward the appropriate electrodes due to applied electric field. For fabrication, p-i-n detectors require high resistivity material and typical photodiodes have thickness ranging from 100 to 500 μm. Important applications of p-i-n detectors include optical sensing of scintillated light in CT scanners, general scintillation spectroscopy, charged particle spectroscopy, and high-speed sensing applications.

**Silicon Drift Detectors**

Silicon drift photodiodes are an extension of the p-i-n geometry and been extensively studied in recent years to provide very low capacitance (<1 pF for 1 cm² detector with 300 μm thickness) [7]. This is achieved by reducing the area of ohmic electrode (anode in most cases) significantly as compared to the entrance electrode as shown in Fig. 56.4(f). Since the charge sensing electronics is connected to the smaller electrode, the device capacitance is proportional to its size and not to the actual detector area. Thus by exploiting this concept, significantly lower capacitance has been achieved than in comparable p-i-n detector.

In drift detectors, it is important to ensure that charges created over the entire active volume will be collected at the anode. In order to achieve this, drift rings are provided around the anode. The outermost ring is biased at highest potential, with the inner rings biased to lower potentials in a successive manner. This arrangement creates a potential minimum at the anode and thereby enables efficient charge collection over the entire detector volume. A variety of device geometries are being explored based on this concept and in some instances these detectors are capable of providing position sensitive detection as well. While these detectors are in the research stage, excellent performance has been demonstrated by prototype detectors. These detectors, when they are commercially available, will have the potential of replacing p-i-n diodes in many applications.
**Silicon Avalanche Photodiodes**

While the conventional silicon diodes, such as \( p-n \) junction diodes, \( p-i-n \) diodes and drift diodes, have no gain, silicon avalanche photodiodes (APDs) have internal gain that enables them to operate with high signal-to-noise ratios and also places less stringent requirements on supporting electronics. In its simplest form, an APD is a \( p-n \) junction operated close to its breakdown voltage in reverse bias. When photons are absorbed in silicon, electron-hole pairs are produced and are accelerated by the high electric field. These electrons gain sufficient velocity to generate additional free carriers by impact ionization, which provides the internal gain. APDs with small areas (few mm diameter) can be manufactured with standard planar processing and have a gain of a few hundred. These detectors are widely used in the telecommunications industry. It is difficult to fabricate high gain detectors with large areas using the planar process; however, special detector designs with beveled edges (see Figure 56.4) have been fabricated to provide high gain (>10,000) in large areas (>1 cm\(^2\)) [8]. The APD gain versus bias behavior for such a device is shown in Figure 56.9. Recent advances in surface preparation and dead layer reduction have extended the application of these detectors to the UV region. While they are relatively expensive, these detectors are well suited to a number of commercial applications such as medical imaging, astronomy, charged particle and x-ray detection, scintillation spectroscopy, and optical communications.

**Amorphous Silicon Detectors**

While impressive results have been obtained with various device structures on crystalline silicon such as drift detectors, APDs, and CCDs, they are limited to active areas of only a few square centimeters. As a result, considerable attention has been devoted to development of hydrogenated amorphous silicon (a-Si:H) [4]. This material is produced by an RF plasma technique in large areas (30 cm \( \times \) 30 cm) on glass substrates. The films are typically a few micrometers in thickness, although films as thick as 200 \( \mu \)m has been reported. Device structures such as \( p-n \) junctions were developed initially for use in solar cells with lower cost than crystalline silicon devices.

Recently, more complicated devices such as \( p-i-n \) sensors and thin film transistors (TFTs) have been fabricated from a-Si:H and have been configured in an array format as shown in Fig. 56.10. In these arrays (as large as 20 cm \( \times \) 20 cm), each pixel consists (200 to 500 \( \mu \)m) of a \( p-i-n \) sensor connected to a TFT, and the entire array is read out in matrix fashion. These arrays are well suited for high-resolution document imaging and also for medical x-ray imaging applications with phosphors.

Novel Materials for Photodiodes and Bandgap Engineering

Important requirements for photodiodes include high quantum efficiency (QE), good charge collection efficiency, and low noise. The low noise requirement is satisfied by reducing detector capacitance and its dark current. In order to satisfy the QE requirements over a wide range of wavelengths, new semiconductor materials are being extensively investigated [9]. Since most semiconductors show high optical response near their bandgap, special materials are developed for various applications. Furthermore, since the bandgap represents a cut-off point in the optical response of the material, by selecting an appropriate material, it is possible to obtain response in a desired band [10]. For example, materials such as GaN and SiC are being explored to obtain UV detection with no sensitivity in the visible region. Other materials are being studied to exploit their unique properties such as high quantum efficiency, high-temperature operation, and high-speed response.

GaN

GaN is an attractive material for UV photodiode fabrication due to its wide bandgap \( E_g = 3.4 \text{ eV} \). Due to the difficulty in growing bulk crystals of GaN, much of the work is done with films of GaN prepared by chemical vapor deposition or molecular beam epitaxy [11]. A variety of optical devices (e.g., blue LEDs and lasers, field effect transistors, photoconductive detectors, and photodiodes) have been fabricated using GaN films. GaN photodiodes have the capability of solar blind UV detection and are capable of fast response time due to high electron mobility (as high as \( 1000 \text{ cm}^2\text{V}^{-1}\text{s}^{-1} \)), which is comparable to silicon.

SiC

SiC is another material that has shown promise for UV detection due to its wide bandgap \( E_g = 3.0 \text{ eV} \) and \( 3.2 \text{ eV} \) for 6H and 4H phases, respectively) [12]. Various optical devices such as blue LEDs, lasers, and UV photodiodes have been developed from 6H-SiC due to the relative ease of doping this material to form \( p \) and \( n \) layers by ion implantation or epitaxial methods. SiC devices are also capable of high-temperature operation, and the photodiodes have shown high quantum efficiency (\( >80\% \)) in the 250 to 280 nm region. Low dark current is another attractive feature of these devices.

InI

Indium iodide is a wide bandgap semiconductor \( E_g = 2.0 \text{ eV} \) being developed for detection in visible and near-UV region [13]. The resistivity of the material is quite high (\( >10^{10} \Omega-\text{cm} \)) and Schottky diodes...
are fabricated using evaporated palladium electrodes. Because of the high resistivity, it is possible to deplete relatively large thickness (0.5 to 1 mm) at low bias (<200 V). One of the unique properties of InI photodiodes is their high quantum efficiency (>70%) in the 300 to 600 nm wavelength region, as shown in Figure 56.11, which in combination with its low dark current makes it attractive for low light level detection applications such as scintillation spectroscopy.

**Alloys and Bandgap Engineering**

In many instances, required properties are attained by bandgap engineering where two or more semiconductors are alloyed together to create a *ternary semiconductor*. The use of a ternary semiconductor provides the ability to tune the peak wavelength of a photodiode. When two binary compounds are combined, the resulting ternary material usually has properties that lie between those of the constituent binary compounds. Examples of some alloys developed in this manner include Hg$_x$Cd$_{1-x}$Te for infrared detection, which is created from HgTe ($E_g = 0.14$ eV) and CdTe ($E_g = 1.45$ eV), Si$_x$Ge$_{1-x}$ which is a mixture of Si ($E_g = 1.1$ eV) and Ge ($E_g = 0.7$ eV) for infrared and visible detection, and TlBr$_x$I$_{1-x}$ which is a mixture of TlBr ($E_g = 2.7$ eV) and TlI ($E_g = 2.1$ eV) for visible detection. A discussion of some recent novel materials that are being developed is presented in the following section and a compilation of relevant properties of various semiconductor materials is presented in Table 56.3.

**III–V Ternary Materials**

Ternary alloys of GaN and AlN ($E_g = 6.2$ eV), Ga$_x$Al$_{1-x}$N, are also being investigated to create optimized UV detectors for desired wavelengths. In the ternary compound, the bandgap depends on the material composition or $x$ and varies almost linearly from 3.4 to 6.2 eV. Such bandgap engineering is desirable to create material with required photoresponse. These devices are also expected to be capable of high

![Quantum efficiency of an InI photodiode.](image)

**FIGURE 56.11** Quantum efficiency of an InI photodiode. The QE peaks at over 80% near the band edge and has a spectral sensitivity of about 70% into the near-UV.
temperature operation due to the wide semiconducting bandgap of the material. Similar devices are also been studied from GaP ($E_g = 2.1 \text{ eV}$) and AlP ($E_g = 2.9 \text{ eV}$) for visible and near UV detection.

Another example is indium gallium arsenide, which is a mixture of InAs ($E_g = 0.36 \text{ eV}$) and GaAs ($E_g = 1.43 \text{ eV}$) and has been recently commercialized as an infrared detector material in the 1000 to 1700 nm region. InGaAs photodiodes in $p-n$ diode, $p-i-n$ diode, and avalanche photodiode configurations are available. InGaAs photodiode arrays coupled to amorphous silicon TFTs are being developed for large area infrared imaging. Other ternary III–V materials that have been investigated for similar reasons include GaAsP, GaNP, and BNP.

**Heterojunction Photojunction Detectors**

A heterojunction is a junction that exists at the interface of two different semiconductors. This concept can be exploited to produce photodiodes with unique properties such as tuned optical response in the region of interest (by adjusting the composition), and reduced optical absorption at the entrance (by irradiating the wider bandgap semiconductor that is transparent to the optical signal). A number of optical sensors have been fabricated using the heterojunction concept using mostly III–V compounds that can be tuned in composition to create heterojunctions with similar lattice constants in both the semiconductors. The research in the heterojunction devices has been aided considerably by the progress in molecular beam epitaxy. One unique application of the heterojunction concept is to fabricate detectors that have capability of distinguishing wavelengths above or below a certain level. This has been accomplished using a multilayer device (see Figure 56.12) that consists of two layers of $\text{Ga}_{x}\text{In}_{1-x}\text{As}_y\text{P}_{1-y}$ which have different composition and, therefore, different bandgaps. The layer Q1 has a larger bandgap than Q2 and both are grown on InP. The optical response of this device when irradiated through the InP substrate is shown in Figure 56.12 and shows minimal overlap in the desired bands indicating successful wavelength discrimination.

Defining Terms

**Bandwidth, B:** The range of frequencies over which the photodiode operates.

**Breakdown voltage, \( V_b \):** The reverse bias voltage at which the applied field overcomes ability of the junction to block current and the device acts like a resistor. The reverse leakage current increases abruptly near this voltage.

**Dark current, or reverse leakage current, \( I_d \):** The leakage current through the device when at the operating voltage with no incident signal.

**Depletion region thickness:** The depth of the depleted portion of the diode when at the operating voltage. Photodiodes are frequently operated fully depleted.

**Junction capacitance, \( C_j \):** Capacitance of the photodiode which decreases as the depletion width increases.

**Noise equivalent power, NEP:** The incident power that generates a signal equal to the noise, i.e., signal-to-noise ratio (S/N or SNR) equals 1.

**Operating bias:** The applied voltage at which the device operates.

**Peak wavelength:** The wavelength with the highest quantum efficiency.

**Quantum efficiency, \( \eta \) or QE:** The efficiency of converting photons incident on the photodiode into electrons that are detected. Reflection of light from the surface and loss of electrons in the semi-
Conductor reduce the efficiency. Reflection losses can be minimized using an antireflection coating on the surface of the device.

**Responsivity (amps/watt):** A measure of the signal current produced as a function of the optical power incident on the photodiode.

**Spectral response:** The quantum efficiency as a function of wavelength.

**Introduction**

**Use of CCDs for Precision Light Measurement**

Charge-Coupled Devices (CCDs) have become the detector of choice for sensitive, highly precise measurement of light over the electromagnetic spectrum from the near-IR (<1.1 µm) to the x-ray band (up to 10 keV). Key advantages of CCDs over their predecessors (photographic emulsions and vacuum tube, electron beam readout devices such as Vidicons and SIT tubes) are high quantum efficiency, high linearity, large dynamic range, relatively uniform cosmetic response, low noise, and intrinsically digital image capture.
CCDs were initially designed as serial data storage media (an electronic analogy to the magnetic Bubble Memory units) in which charge packets were injected into linked capacitors to store data, and read back by moving the packets back out of the device. When it was found that charge packets could be directly induced in the capacitors by exposing them to light, the CCD as light sensor was born.

Physically, CCD operation consists of four critical stages. First, an incident light photon must be photoabsorbed in the sensitive portion of the CCD chip (called the depletion region). At optical and infrared wavelengths, the absorption results in a single electron being promoted into the conduction band (leaving a hole in the valence band); at shorter wavelengths, the photon has enough energy to make additional electrons via secondary ionizations by the photoelectron.

Second, the photon-induced electrons must be collected, via an electric field within the silicon, into localized regions near the front surface of the chip. The electric field is shaped by implanted dopants and by electric potentials applied to thin conducting strips (gates) that prevent the electrons from diffusing away. The resulting charge distribution corresponds to an electronic analog of the light intensity pattern shone on the CCD. The resolution of this pattern is governed by the size of the potential wells, which are designed to be periodic. Each well is called a pixel and corresponds to the minimum picture element detected by the CCD.

Third, after exposure is completed, the CCD charge pattern must be transferred out of the CCD. This is accomplished by modulating the potential applied to the CCD gates in such a way that no charge packets are mixed, but that each packet moves into the next pixel. The end pixel is transferred into a special pixel array called the serial register. Each movement of charge resulting from gate potential changes is called a clock cycle, and the serial register receives many clock cycles for each cycle of the full pixel array. The net result is a sequence of charge packets emerging from the serial register, each of which is directly proportional to the amount of light striking a particular location on the CCD.

Fourth, the emerging charges are converted into electric signals by a charge-sensitive preamplifier on the CCD chip. These signals are often digitized by electronics in the camera immediately outside the chip, but analog readouts that produce signals compatible with video standards are also used (the popular hand-held video cameras are examples of this). Research-grade camera readouts are able to measure the charge pulses with accuracies as good as one or two electrons rms, if the CCD and electronics are cooled.

Currently available CCDs carry out these steps so well that they are nearly the ideal detector for precision low light level applications, especially in astronomy. Such an ideal detector would have perfect quantum efficiency (i.e., convert every incident photon into detectable signal), no noise, unlimited dynamic range, linearity in response to incident intensity and position, and completely understandable characteristics.

CCDs have high quantum efficiency because photons interact via photoabsorption in the depletion layer, which directly results in one or more electrons promoted into the conduction band of the silicon lattice, and are very efficiently collected by the CCD. The main obstacles to perfect quantum efficiency are absorption of photons by the gate and insulator materials before they ever reach the depletion regions (or optically, by reflection off the front surfaces) or if the photon passes entirely through the depletion region without interacting.

There are many approaches to enhancing CCD quantum efficiency for various applications. In soft x-ray and ultraviolet wavelengths, the gate and insulator layers on the front of the CCD absorb too much light. To solve this, CCDs are built with thin gates or thinned substrates and back-side illumination. CCDs are also coated with phosphor coatings that down-convert ultraviolet light to longer wavelengths where the gate transmission is higher.

At hard x-ray and infrared wavelengths, too much light can pass through the depletion region without interacting at all. The depletion region is the part of the CCD pixel that is swept clean of free charges during the readout process. The depletion region gets deeper if higher purity silicon is used, and if higher voltage biases are applied during the readout.

Above 1.1 µm, photons do not have sufficient energy to promote electrons into the silicon conduction band, so other materials, such as germanium or a compound semiconductor such as InAs, InSb, or HgCdTe must be used.
CCD noise results from four major factors: (1) thermal background noise, (2) charge transfer imperfections, (3) charge-to-voltage amplification noise, and (4) cosmetic imperfections in the CCDs due to, for example, microscopic shorts in the insulating layers of the CCD. Factor (1) results from a “dark current” of thermally excited electrons that accumulate in the pixels and can be eliminated by cooling the CCD (typically to −60 to −120°C). Factor (2) results from traps that hold electrons long enough to shift them into following charge packets identified with other pixels. Factor (3) is a fundamental limit related to the temperature and capacitance of the output mode (\(kT/C\)), but it can be suppressed by signal processing techniques such as “correlated double sampling” to the equivalent of a few electrons (1–5 in state-of-the-art cameras). Factors (2) and (4) can be greatly reduced by improved manufacturing technique, especially scrupulous contamination control during the process.

CCD dynamic range is set by the maximum charge packet that can be stored in a pixel. Termed “full-well capacity,” this is set by the depth of the potential well. When the full-well capacity is exceeded, the image of a point source “blooms” as a result of charge leaking into surrounding pixels, and a trail of brighter pixels forms in the readout direction of the CCD due to charge incompletely transferring from pixel-to-pixel during a clock cycle. Modern CCDs have full-well capacities in excess of \(10^5\) electrons and can be designed even larger. (Note that larger full-well also requires larger output capacitance, so a trade-off is generally required between blooming and low noise.)

CCD linearity in intensity response and position response is very good because the conduction band in the CCD has so many states that the very small injected photocharge does not affect subsequent photon interactions. The position linearity results from the photolithography of the manufacturing process, which must be accurate to less than 1 µm. The primary limitation on linearity results from imperfect charge transfer efficiency (CTE) in the process of clocking charge packets from pixel to pixel. At readout rates below 100,000 pixels per second, CTE imperfections have four causes.

1. Design imperfections: errors in CCD design can leave potential minima that are incompletely drained during clocking.
3. Bulk traps: lattice defects or impurities that introduce local potential minima, which temporarily capture electrons long enough to remove them from the original charge packet, but re-emit them later.
4. Radiation-induced traps: similar to (3) but resulting from lattice defects caused by low-energy protons. This damage is most commonly seen by spacecraft CCD cameras.

**CCD Operation and Data Reduction**

In order to achieve ultimate CCD performance for a given goal, the CCD camera can be operated in special ways, and the postcamera data reduction can be optimized. Typical optical use of CCDs involves timed exposures, where the CCD pixels are exposed to light and the total charge integrated in pixels for a preselected time. At the conclusion of the integration, a shutter closes and the CCD is read out. As noise reduction limits the readout to roughly 100 kpixels/s, a large CCD (2048 \(\times\) 2048 pixels) readout can take many seconds to complete.

To avoid the deadtime associated with the closed shutter, some CCDs are made with framestore regions. The framestore is a pixel array equal to the integration region which is permanently blocked by a cover from any additional light. The pixels containing the charge pattern resulting from the integration are very rapidly clocked into the framestore region (typically requiring much less than 1 s) and then slowly clocked out into the readout region without moving the integration pixels.

Operationally, CCD reduction requires calibration exposures. These include bias frames, which are readouts with the same integration time but no light striking the CCD, and flat field frames, which have a uniform illumination over the CCD. The bias frames are subtracted from the data frames to set the zero-point corresponding to zero incident radiation. (Note that CCDs will accumulate charge due to thermal electrons and low-level shorts in the gates, even if no light hits the CCD.) The flat field allows
correction for pixel-to-pixel sensitivity variations. Proper flat fielding can remove variations of arbitrary amplitude and spatial scale.

The CCD dark current bias can be reduced by cooling the CCD, or by operating it in an inverted phase mode. In inverted phase operation, the gate electrode is given a suitable negative bias that attracts hole carriers to the front surface of the CCD. These holes fill interface states at the Si–SiO₂ boundary between the conducting depletion region and the insulating layer under the gates. Suppression of these interface states dramatically lowers the dark current because the interface states are much more efficient at thermal electron promotion to the conduction band than the bulk material. Not all phases can be operated in inverted mode in a normal CCD because, without the restraining potentials provided by gates held at positive voltage, the pixel charge packets can intermingle. A special CCD called an MPP (multiphase pinned) device has extra implant doping that isolates the pixels even with all three phases inverted, yielding dark current so low that integration times up to minutes become possible in room-temperature MPP CCDs.

Other important uses of CCDs include cases where the CCD is continuously clocked, without any shutter. Suitable for high light level conditions, the effective integration time becomes the time to transfer a pixel charge across the source point spread function on the CCD. This allows sensitive timing of source intensity changes.

A similar technique is called drift scanning, where the rate of clocking of pixels equals the rate of motion of the target across the CCD. Such a condition is common in astronomy, where a fixed detector on the Earth sees slow motion of stars in the field of view due to the Earth’s rotation.

Drifts and instabilities in the camera electronics can be corrected using a technique called “overclocking.” If the serial registers are clocked more times than there are physical pixels in the CCD, then the excess clocks will produce charge pulses corresponding to zero input light and zero dark current. The distribution of the overclock pulse is then a measure of the readnoise of the CCD chip-camera system, and the mean of the distribution sets the zero point of the energy to output voltage curve. Frequently, CCD cameras subtract the mean of the overclock pixels from all output values in a row (called “baseline restoration”).

**CCD Signal-to-Noise Ratios (SNR)**

To see how these characteristics of the CCD relate to measurement, it is instructive to study the SNR predicted for a given exposure time. In a single pixel illuminated by a source that contributes \( S_o \) counts (electrons) to the pixel, one also sees contributions from dark current \( S_d \) and background illumination \( S_s \), usually called the “sky” in astronomical usages), all in units of counts per pixel per second. The source contribution \( S_o \) can be expanded into the intensity of light from the source, \( I \); the quantum efficiency of the CCD, \( Q \); and the integration time, \( t \), to provide

\[
S_o = I \times Q \times t
\]

The camera readout contributes a randomly distributed but fixed Gaussian noise with variance \( N_r \). The SNR of a particular pixel is then:

\[
SNR = I \times Q \times t = (I \times Q \times t + N_r^2 + S_d + S_s)^{1/2}
\]

If the light from a source is distributed over a number of pixels, \( n \) [as might arise from a star viewed through a telescope with a point spread function (PSF) covering \( n \) pixels], then if the integral of \( S_o \) over the PSF is \( C_o \), and the integral of \( S_s \) over the pixels is \( C_s \), then

\[
SNR = C_o^{1/2}/(1 + C_sC_o + n + r^2C_o)^{1/2}
\]

Clearly, high \( Q \) and low \( r \) are desirable, and \( t \) should be chosen to make \( C_o \) greater than both \( C_s \) and \( r \). It is worth noting that, in most optical applications (except for extremely faint sources), it is the
uncertainty in the flat fielding (i.e., the corrections made for pixel-to-pixel sensitivity variations and background) that ultimately limits the achievable SNR.

**CCD Structure and Charge Transport**

**CCD structure and its potential profile under bias**

A CCD is a semiconductor device operating under the principle that charges can be temporarily stored and transported along a string or array of MOS capacitors. The basic storage unit is called a pixel and is made up of several MOS capacitors. In almost all CCDs, charges are stored either directly at the oxide–semiconductor interface (surface-channel device), or deeper within an epitaxial layer (buried-channel device). Theoretically, a surface-channel CCD has a larger charge capacity, but it also is prone to noise arising from interface states at the boundary.

The CCD is operated by varying voltages applied to the surface electrodes. Typically, the CCD is kept for a long period in an integration state, where photon-induced electrons accumulate in the potential wells under the CCD pixels. After the integration finishes, the voltages are changed to transport the charge from one capacitor to the next. This sequence of moving charge packets by potential clocking is sometimes called “bucket-brigade” charge transfer.

The storage unit of the CCD is the MOS capacitor and it is possible to deplete, invert, or form a surface accumulation layer in the MOS capacitor by simply changing the surface potential. CCDs operate in the so-called “deep depletion” mode when the surface layers are fully depleted. For a buried-channel CCD with an $n$-type buried layer within a $p$-type epilayer, this would require the application of a positive bias to the surface electrodes. The equations governing the one-dimensional calculations of the potential distribution in the MOS capacitor are [1]:

\[
\frac{d^2 \psi}{dx^2} = 0 \quad -d < x < 0
\]

\[
\frac{d^2 \psi}{dx^2} = -q \cdot \frac{N_D}{\varepsilon_s} \quad 0 < x < t
\]

\[
\frac{d^2 \psi}{dx^2} = q \cdot \frac{N_A}{\varepsilon_s} \quad t < x < x_p
\]

where $\psi$ is the potential, $N_A$ is the substrate acceptor density, $N_D$ is the donor density in the epilayer, $x_p$ is the depletion edge in the $p$-type substrate, and $\varepsilon_s$ is the semiconductor permittivity. Note also that $d$ is the oxide thickness and the origin ($x = 0$) is located at the oxide–semiconductor boundary.

The boundary conditions will be:

\[
\psi(x = -d) = V_G \quad \frac{d\psi}{dx}\bigg|_{x = t^-} = \frac{d\psi}{dx}\bigg|_{x = t^+}
\]

\[
\varepsilon_{ox} \cdot \frac{d\psi}{dx}\bigg|_{x = 0^-} = \varepsilon_s \cdot \frac{d\psi}{dx}\bigg|_{x = 0^+} \quad \psi(x = t^-) = \psi(x = t^+) \quad \psi(x = 0^-) = \psi(x = 0^+) \quad \psi(x = t + x_p) = 0
\]
and the solutions are:

\[
\begin{align*}
\psi &= V_G - E_{\text{ox}} \cdot (x + d) & \quad -d < x < 0 \\
\psi &= \psi_{\text{max}} - q \cdot N_D \cdot (x - x_p)^2/(2\varepsilon_s) & \quad 0 < x < t \\
\psi &= q \cdot N_A \cdot (x - t - x_p)^2/(2\varepsilon_s) & \quad t < x < t + x_p
\end{align*}
\]

(56.22)

where \( E_{\text{ox}} \) is the electric field in the oxide layer, \( V_G \) is the gate bias voltage, and \( x_n \) is the position of the potential maximum.

Figure 56.13 shows a typical potential profile across the MOS capacitor in a buried-channel CCD. Note the presence of a potential maximum, \( \psi_{\text{max}} \), where the electrons will reside. It is given by:

\[
\psi_{\text{max}} = \psi_t \cdot (1 + N_A/N_D)
\]

(56.23)

where \( \psi_t = q \cdot N_A \cdot x_p^2/(2\varepsilon_s) \). Since \( x_p \) increases linearly with \( N_D \), the potential maximum \( \psi_{\text{max}} \) and hence the charge storage capability also increases for a heavily doped epilayer. The derivation of the potential profile in a surface-channel CCD will be similar, but with \( d \) set to zero.

**Charge Transport**

Charge transport in a CCD refers to the transfer of charges along the MOS capacitors (i.e., from one pixel to the next). There are several clocking schemes used, generally divided according to how many external voltage regions are applied per pixel, ranging from one (uni-phase) to four-phase.

Computation of charge transport in a CCD requires solving the two-dimensional Poisson equation with appropriate boundary conditions to obtain the potential distribution within the pixel for each separate phase within the clocking cycle. Numerical techniques using finite-difference or finite-element methods have been used. For charge transfer in an \( n \)-type epilayer, the electron flux, \( F(x) \), is given by:

\[
F(x) = n_e(x, t) \cdot u(E(x)) - D(E(x)) \cdot (n_e(x + \Delta x, t) - n_e(x, t)) = \Delta x
\]

(56.24)

where \( n_e(x, t) \) is the electron density, \( E(x) \) is the electric field in the \( x \)-direction, \( u(E(x)) \) is the field-dependent velocity, and \( D(E(x)) \) is the electron diffusivity. Figure 56.14 shows the time evolution of charges along a CCD. Some “smoothing” of the output charge profile is often observed and, for high-

![Potential profile across MOS capacitor.](image)
speed devices, velocity saturation will be important. Computations of charge transfer are sometimes carried out using an equivalent circuit model for the CCD in a SPICE-type simulator. It has been shown to offer both faster computation time and the ability to include external support circuits into the model.

Charge transfer efficiency, $\eta$, is the key figure-of-merit in a CCD, at least comparable to quantum efficiency. A common technique to determine $\eta$ is to measure the amplitude response of the CCD using a network analyzer. $\eta$ is then related to the amplitude response of the output, $G_c$, through the following relationship:

\[ \eta = \frac{G_c}{A} \]

FIGURE 56.14 Time evolution of charges along a CCD: (a) $t = 200$ ps; (b) $t = 400$ ps; (c) $t = 600$ ps.
where \( N_T \) is the number of transfers, \( f \) is the signal frequency, and \( f_c \) is the clock frequency. For the relatively mature Si CCD technology, charge transfer efficiency of 0.99999 can be easily achieved. Note, however, that this analysis applies to sinusoid illuminated scenes and test signals, but does not apply to delta function injections of charge that are infrequently transferred, as applies to the x-ray photon-counting case.

**Input and Output Structures**

The input structure of the CCD usually consists of a \( p-n \) junction and two or more input gates as shown in Figure 56.15. Initially, when the input voltage, \( V_{id} \) is pulsed low, charges will flow through the input (electrode) into the potential well created under the input gates \( G_1 \) and \( G_2 \). When \( V_{id} \) returns to its equilibrium value, charges will be withdrawn except those residing in the potential well formed by the potential difference between \( G_1 \) and \( G_2 \). Charge injection is now complete and a drop in the potential \( \Phi_1 \) at the transfer gate will allow charges to enter into the first CCD pixel. The input charge, \( Q_{in} \), is approximately given by:

\[
Q_{in} = C_{ox} \cdot (V_{G1} - V_{G2})
\]

where \( C_{ox} \) is the oxide capacitance, and \( V_{G1} \) and \( V_{G2} \) refer to the voltage difference between \( G_1 \) and \( G_2 \). In CCD sensors and detectors, signal input normally relies on the incident photons liberating charge within the depletion region (after traversing either the front gates [front-illuminated] or the back surface [back-illuminated]). Charges so created will be collected in the potential wells formed by the clock voltages.

Normally, the output structure of the CCD consists of a reset switch and a floating diffusion (FD) or floating gate (FG) amplifier. These are shown in Figure 56.16. During sampling, the output charge flows into the floating node and a voltage is developed across the output capacitance, which is a combination of the depletion capacitance of the floating node and the input gate capacitance of the source follower. In general, the voltage output, \( V_{sig} \), can be expressed as:

\[
V_{sig} = Q_{inj} \cdot A_V / C_{fd}
\]

where \( Q_{inj} \) is the injected charge, \( A_V \) is the small-signal voltage gain of the output amplifier, and \( C_{fd} \) is the capacitance between the floating node and ground. Since both \( A_V \) and \( C_{fd} \) are sensitive to the output
Improvements in the output structure can be achieved using either a floating gate amplifier or Miller feedback at the output to reduce parasitic capacitances.

**Noise in CCDs**

CCD noise will degrade the SNR. The following are important noise sources in CCDs:

1. Thermal noise, or dark current, is due to thermally excited electrons that accumulate in the pixels during the integration. In applications where the clocking time is short compared to the integration time, the equivalent noise electron, $n_{th}$, is given by:

   $$n_{th} = \sqrt{J_d \cdot A_E \cdot t_{int}}$$

   where $J_d$ is the leakage current density, $A_E$ is the area of the transport electrode, and $t_{int}$ is the integration time. A lowering of the operating temperature will normally reduce the leakage current density and hence the equivalent noise electron.

2. Bulk traps are the dominant noise sources for buried-channel CCDs and the equivalent noise electron from this source is:

   $$n_{trap} = \sqrt{N_t \cdot V_{sig} \cdot e^{\frac{T_i}{\tau}} \cdot \left[1 - e^{\frac{-T_i}{\tau}}\right]}$$

   where $V_{sig}$ is the volume of the charge packet under the transfer electrode, $N_t$ is the density of the bulk trap states, $T_i$ is the transfer time, and $\tau$ is the electron emission time constant. It can be observed that the equivalent noise electron increases as the size of the charge packet increases, an indication that bulk traps do not generally affect the SNR in CCDs. In x-ray photon counting applications some effects of bulk trapping noise have been seen.

3. Both the input and output of a CCD involve charge storage across capacitors that will be affected by fluctuations in the circuit. The equivalent noise electron for this process is:

   $$n_{inp} = \sqrt{kT \cdot C_{inp}} \quad n_{out} = \sqrt{kT \cdot C_{out}}$$

---

**FIGURE 56.16** Output structures of a CCD.
where $kT$ is the thermal voltage and $C_{inp}$ and $C_{out}$ are the input and output capacitances. A special signal processing technique known as “correlated double sampling” can be used to reduce this $kTC$ noise at the CCD output.

1/f noise is also present in the output amplifier and is only significant at low frequencies. Methods to reduce 1/f noise include multiple sampling using distributed floating-gate amplifiers (DFGA) [2] and noise cancellation techniques using alternate gain inversion (AGI) [7].

4. The maximum SNR of a CCD is limited by the maximum amount of charge that can be stored in a pixel, divided by the equivalent noise electron. Expressed in decibels, it is:

$$\text{SNR} = 20 \log(Q_{\text{max}} = Q_{\text{noise}})$$

The maximum charge is:

$$Q_{\text{max}} = C_c \cdot \psi_{BH}$$

where $C_c$ is the depletion capacitance associated with the electrode, and $\psi_{BH}$ is the depth of the potential well.

**CCD Power Dissipation**

CCD power dissipation is primarily linked to the charging and discharging of the gate capacitances. This power is mainly consumed by the clock driver and is given by:

$$P_{\text{clock}} = C_c \cdot V^2 \cdot f_c$$

where $C_c$ is the clock line capacitance associated with the electrodes, $V$ is the clock voltage, and $f_c$ is the clock frequency. For $f_c = 100$ MHz and $V = 5$ V, typical values of $P_{\text{clock}}$ are 50 µW per pixel.

In addition to $P_{\text{clock}}$, the on-chip power dissipation per pixel is approximately given by:

$$P_{\text{CCD}} = nq(f_cL)^2/\mu_c + 2nqf_c(\psi_{BH} - nq/(2C_c))$$

where $n$ is the number of electrons in a pixel, $L$ is the pixel length, and $\mu_c$ is the electron mobility. The overall power dissipation in a CCD is therefore the sum of $P_{\text{clock}}$ and $P_{\text{CCD}}$.

**CCDs Applications to Light Sensing**

**Optical Imaging and Spectroscopy**

The many fine properties of CCDs have made them the detector of choice for the recording and readout of images at both high and low light levels. The applications include (1) reconnaissance, both civilian and defensive, (2) scene and personnel monitoring, (3) robotics, and (4) astronomy. In astronomy, CCD cameras have found their way into almost all observatories in the world, both for direct readout of images and as the readout cameras for spectrographs.

Perhaps the most exacting application of CCDs has been to astronomy, a discipline in which the characteristics of the CCD need to be pushed to their limits in order to gain the optimum performance. As well as the attempt to optimize this performance in order to gain as much science as possible from the images, it has also been crucial to calibrate the devices as precisely as possible and to fully understand their behavior. In this sense, astronomy has been the “driver” for the scientific development of CCDs. Large-scale commercial applications, such as video recorders, monitoring cameras, etc., have driven the need for improved manufacturing yield, blemish-free operation, uniformity in performance, and reliability.

In order to illustrate the importance of CCDs to exacting scientific requirements, this section will focus largely on the applications to astronomy.
The early demonstration of the performance of a commercial CCD at the focus of a telescope quickly led to the realization of their potential for both space and ground-based astronomical cameras and instruments. Fortunately, this development in the early 1970s was just in time for the first major optical observatory in Earth orbit, the Hubble space telescope (HST). Perhaps the most spectacular application of CCDs to visible light imaging has been within the cameras on board this telescope, i.e., the wide field and planetary cameras built at the Jet Propulsion Laboratory. The CCDs in these cameras consisted of $800 \times 800$ pixel arrays, with each pixel of size 25 µm. The first version of this camera contained eight thinned, back-illuminated devices that were more or less fully depleted. An accumulation layer at the back surface was achieved by flooding the devices with UV light from a lamp internal to the instrument. This accumulation layer allowed the collection of charge resulting from the photoelectric absorption of blue light, and accelerated the charge to the frontside potential wells. Furthermore, the devices were coated in a down-converting coronene phosphor that converted UV light into the yellow-green wavelength band, thus allowing a 20% efficiency in the UV. These devices thus had relatively high quantum efficiency from the UV through to about 1 µm, vitally important for an instrument collecting photons from galaxies billions of light years away in the universe. As well as their high quantum efficiency, these devices had high charge transfer efficiency and relatively low readout noise at the time of their development. All of these characteristics have since been superseded—at first by an improved version of the camera installed in the HST in late 1993, and then in the Advanced Camera for Surveys, to be installed in 1999. These later instruments had larger format, higher quantum efficiency, and lower readout noise. During the 1980s, devices were developed with these large formats and with readout noise levels approaching one electron.

Starting with modest arrays of size on the order of a few hundred pixels in the 1970s, the devices that became available in the 1990s were as large as 4096 pixels square. As well as in space, these devices have been employed at the prime foci of the world’s largest telescopes to give images covering more than 10 arc minutes on a side while still sampling the atmospheric-limited resolution (arcsecond or subarcsecond) adequately. Such devices, when exposed to the sky for up to an hour through a broadband filter, can produce images with tens of thousands of objects for statistical studies in astronomy.

Typical pixel readout rates for astronomical cameras are of the order of 50 kHz, taking tens of seconds for a full readout. Integration times for astronomical CCD cameras can vary from fractions of a second to tens of minutes or even times in excess of an hour, usually limited by the background noise induced by cosmic ray particles and their secondaries. These cosmic ray “events” can be removed by taking at least two frames of data and cross-comparing them. This is important even on the ground, where the radioactive background and muon-induced events total about one per cm$^2$ per minute; but the cosmic-ray background in space is about one per cm$^2$ per second, so that camera exposures are rarely longer than 10 to 20 min. Sophisticated computer algorithms have been developed in order to remove the effects of this background radiation.

Of special importance to applications in space research is the packaging of the devices. Contamination of the cold CCD surface by as much as a monolayer of a heavy molecule will effectively render the CCD useless in the vacuum-UV, for example. Careful attention must therefore be paid to the local instrument environment. The CCDs on the HST were in hermetically sealed packages, and the contamination problem was transferred to the lenses covering the CCD packages. In order to achieve optimum performance, the overall camera has to be designed to satisfy the exacting requirements of the CCD, from the point of view of thermal control and stability, absence of electronic interference, and rigorous attention to the elimination of water or heavy molecule contamination. For space application, it may also be advantageous to surround the CCD package with a cosmic-ray shield, such as the 1 cm (0.4 inch) of tantalum used in the CCD cameras on the HST and the Galileo mission to Jupiter. Such radiation shields have to be designed with caution, lest they introduce more secondary particles and induced radioactivity than the primary protons that they stop.

Finally, much effort is put into the processing of astronomical CCD data [24]. Special techniques have been developed to calibrate the pixel-to-pixel nonuniformity in quantum efficiency (a function of wavelength), both on large and small scales. With some effort, this nonuniformity can be calibrated to levels...
below 1%. Although it may be easy to expose the CCD to a diffuse source such that there are at least 10,000 electrons per pixel, the corresponding flatfield calibration accuracy may be compromised at low light levels. For astronomical applications, especially in space, most of the pixels may receive only tens of electrons or fewer during an exposure. Low-level traps (including those caused by cosmic radiation) will then manifest themselves in the form of charge-transfer inefficiencies over localized areas or columns. It may be important to calibrate the CCD at the same exposure levels as those typically encountered during the science observation. One way of effecting this is to use hundreds or thousands of frames of data taken in different parts of the sky, and rejecting the astronomical objects in them. These “sky frames” can then be used to produce a “super sky-flat,” which is the average of the individual frames of data.

**CCD X-ray Imaging Spectroscopy**

Scientific applications such as astronomy have been responsible for driving improvements in CCD technology. In the x-ray domain, for example, CCDs are starting to be employed for medical radiography, where the digital imaging capability and high sensitivity allows for lower patient doses and online image processing. As high-resolution readout detectors of dispersive x-ray spectrometers, CCDs are becoming widely used in the new generation of high brilliance synchrotron beamlines. As spectrometers, they are also being considered in some applications as replacement for Si(Li) diodes, where the higher operating temperatures and improved resolution and efficiency down to x-ray energies below 1 keV leads to applications of interest to biological science and technology.

In contrast with optical imaging applications with many photons per charge packet, to measure x-ray spectral information directly with a CCD single photons per pixel per image frame are required. To use the CCD as a nondispersive x-ray spectrometer requires that the correspondence between the magnitude of the electron charge packet generated initially by the x-ray photon, and the signal measured at the CCD output, must be maintained. This places a very stringent requirement on the efficiency of charge transfer. However, even before the process of charge transfer is initiated, the physics of the charge collection may also degrade the energy measurement process.

The absorption process for a photon of energy \( E \) begins with the ejection of a photoelectron, of energy \( E - E_B \) where \( E_B \) is the binding energy of the appropriate silicon atom electron shell. The range of the photoelectron may be only a fraction of 1 \( \mu \)m. In a few percent of cases, a silicon K shell fluorescence photon may be emitted, and this has a range of about 10 \( \mu \)m, so that there is a finite probability of the event energy splitting into more than one pixel.

Eventually, a proportion of the energy is converted to free electrons, the rest into phonons. The average energy to create an electron-hole pair is roughly constant at about 3.6 eV of incident photon energy per pair produced in silicon. If this free electron charge packet is created in the depletion layer of the CCD, it is promptly drifted under the influence of the electric field to the buried-channel collection site. During this drift time \( (t_d) \), the charge can laterally diffuse within a radius \( \sim \sqrt{2D t_d} \), where \( D \) is the diffusion constant. Except for the charge clouds originating deep in the depletion layer, this radius is small compared with the typical pixel size. If the charge is generated in a field-free layer outside the depleted volume, it will radially diffuse until a fraction recombines or reaches the depletion layer. The latter fraction then starts to drift with the same additional lateral drift as the depletion layer charge packets.

The pixel boundaries are loosely defined by the asymmetric fields created by electrode biasing schemes and surface channel stop implants, and not hard physical boundaries. Hence, any lateral spreading processes may allow some splitting of the initial charge packet between pixels. Furthermore, charge loss may be experienced either by the partial recombination of events when liberated deep below the depletion layer, or if the fraction of split charge is too low to be recognized against the device noise level.

In astronomical applications, in space-borne observatories, there is a continuous low-level background of charged particles. Rather than liberating point-like charge clouds, they liberate a population of signal electrons along their tracks throughout the silicon. They may be easily discriminated against x-rays if these tracks are highly skewed with respect to the silicon surface and cross many pixels. Also, if the track is long enough, the magnitude of total charge cloud generated may be large compared with the typical x-ray charge packet.
These features impose a requirement to perform event recognition and analysis. To perform this on-ground would require transmission of all pixel data, including empty pixels, which for megapixel CCD frames generated on second time scales is quite infeasible. Performing this recognition on-board first requires a comparison against some lower threshold. Selection of this level is critical—too high and some split charge may be neglected with a consequent degradation of energy resolution. Too low a threshold, and many spurious events will be counted. If there is a drift or change in the zero-energy signal upon which this threshold is applied, the energy scale may be misregistered, and/or the relative fraction of events selected at different x-ray energies may be unknowingly altered. Simulations show that for the potential energy resolution of CCDs, spectral analysis of cosmic plasmas will demand a calibration of relative detection efficiency versus energy to ~3%. If the threshold value is set at about 4σ times the readout noise, this calibration may be degraded by as little as a single digital bit of a commonly used 12-bit ADC in the CCD readout electronics. Thus, the realtime digital processing of events is required to be fast and complex.

A further complication of the event splitting is that to avoid pile-up in CCD frames, the probability of having multiple events per pixel is made more stringent by requiring surrounding pixels to have no signal, and allow this recognition process. Typically, an event rate of 1 photon per 200 pixels per CCD frame is therefore imposed, but this places a rather low limit on attainable count rate performance. Especially with high-resolution focusing optics of observatories such as AXAF[5], this can be much lower than for many previous experiments. If the core of the point spread function of the mirror is not to be degraded by this effect, then special readout formats that reduce the imaged area, in order to accelerate frame readout times, must be employed.

**Future Improvements to CCDs**

*Backside CCDs*

The useful spectral range of conventional CCD detectors, although quite broad, is limited in part by the presence of the polysilicon gates on the front surface. As is illustrated in Figure 56.17, photons with...
wavelengths in the range $3 \text{ nm} < \lambda < 400 \text{ nm}$ have attenuation lengths in silicon less than the typical thickness of the gate structure ($\approx 0.4 \mu\text{m}$). Photons in this spectral range are therefore absorbed before they can enter the photosensitive volume of the detector. For conventional CCDs, the detection efficiency is no more than a few percent in this band. If the gates can be made thinner by an order of magnitude, or avoided altogether, then the detection efficiency can be improved dramatically in both the very soft x-ray and the UV. Efforts following the former approach are described below. The latter strategy, which requires illumination of the back surface of the CCD (that is, the surface opposite the gates) is discussed here.

There are a number of techniques that can be used to produce back-illuminated devices [10–12], but they must all deal with two constraints: lateral diffusion of the photoelectrons before they are captured in the buried channel of a specific pixel and the tendency for photoelectrons to recombine at the back surface of the Si.

The lateral diffusion of electrons can lead to a loss of resolution of the CCD since they may cross the boundary between one pixel and another, leading to an erroneous assignment of the origin of the photon that created the electron. This problem is minimized by thinning the back-illuminated CCD to thicknesses that are on the order of the depletion depth of the Si, so the least drift occurs before the electron is captured in the potential well of the buried channel. This thinning is accomplished by a combination of methods, including mechanical grinding and polishing and wet etching. Handling of back-illuminated CCDs after thinning, however, is a problem since the remaining Si is between 10 and 100 µm thick, and is not strong enough to support rough handling, or even the intrinsic stresses arising from the initial fabrication of the CCD. To circumvent this problem, rim thinning or frame thinning can be used; in the first case, a rim several millimeters wide around the circumference of the wafer is protected during the thinning process, while in the latter, a region 1 or 2 mm wide around each device is protected.

Lateral diffusion can also be reduced by imposing an electric field through the thickness of the thinned membrane; but if this is done by imposing an electrode on the back surface, then the device will have a reduced QE (quantum efficiency) due to absorption in this layer. The presence of a depletion region in the CCD will also give rise to an electric field, which reduces the lateral diffusion of electrons; but if the desired depletion region is on the order of tens of micrometers, in order to image high-energy x-rays or IR photons, then the induced field will be small, due to the low doping levels in the silicon and Gauss' law.

Although the lateral spread of photoelectrons is a problem, the loss of carriers to recombination at the back surface presents a greater technical difficulty. The recombination velocity can be minimized by introducing a strong electric field at the back surface and by passivating this surface. There are several methods employed to generate this electric field: one is by implanting carriers ($p$-type for the case where photoelectrons are to be captured) and annealing the sample to activate these carriers [11], a second is to deposit a thin layer of metal with the appropriate work function difference (typically Pt or another transition metal) [10], while a third method is to grow a heavily doped epitaxial layer on the back surface [13]. In the implant method, strong electric fields can be generated and the annealing process can help to passivate the back surface, but high-temperature annealing of the wafer can present a problem if metallization is present, unless excimer laser annealing is employed [14]. Deposition of a thin metallic layer can lead to long-term instability of QE and does not appear to yield the highest QEs. Deposition of an epitaxial layer relies on the use of sophisticated equipment and surface cleaning methods.

In addition to introducing an electric field on the back surface, it is necessary to electrically passivate that surface to lower the electron recombination velocity. Again, there are several approaches. The flash gate technique is probably the simplest, relying on inserting the sample in a steam atmosphere, but it is not stable over time [10]. Another method is to grow a high-quality oxide on the back surface [11], but this requires the use of high temperatures, which could melt metalizations and allow any dopant layer to diffuse too deeply into the silicon.

Although the aim of the backside treatment process is always to maximize the fraction of charge collected from the vicinity of the back surface, there are subtle differences in requirements that depend on the application. In the UV ($100 \text{ nm} < \lambda < 400 \text{ nm}$), the extremely small attenuation lengths (see Figure 56.17) place a premium on nonnegligible (>~50%) charge collection efficiency very close to the back surface. Therefore, in UV sensors, the field in the immediate vicinity of the back surface is extremely
important. Moreover, the real part of the index of refraction of silicon is quite high in the UV and optical bands, and Fresnel reflections limit the external detection efficiency that can be achieved. Thus, significant improvements in the UV response of back-illuminated CCDs have been obtained via the application of antireflection coatings as a part of the backside treatment process [12].

In the very soft x-ray range (2 nm < \( \lambda \) < 100 nm), the attenuation length can be larger by a factor of 10 than in the UV. Moreover, the range of the secondary photoelectrons is large enough to be comparable to the attenuation length [15], so the physics of the secondary ionization process becomes important. Thus, in the very soft x-ray regime, it is the average properties of the device over scales of a few hundred nanometers that determine performance. However, for spectroscopic applications, the theoretical limit of device performance cannot be reached unless the charge collection efficiency substantially exceeds ~90%. Thus, in the soft x-ray, one requires very high collection efficiency over a relatively large volume in the vicinity of the back surface.

Any backside fabrication techniques will probably require compromises to be made, but it is possible to achieve very high external QE in the UV, as shown in the accompanying Figure 56.18, and in the soft x-ray region where 77% QE has been achieved at 277 eV [16]. Further improvements are necessary to achieve good results in the vacuum UV and theoretical limits for energy resolution in the soft x-ray. These improvements are possible, but will probably depend on the continued development of sophisticated processing tools.

**Thinned Gate CCDs**

Recently, a new type of CCD was developed that was optimized for spectroscopy below 1 keV. This detector, called a thin gate CCD (or TGCCD), contained two novel features: floating gate output amplifiers (FGAs or “skippers”) and thin gates (electrodes) [2]. The goal was to develop a detector that had Fano-limited energy resolution with nonnegligible QE over the 200 eV to 1000 eV bandpass. This section briefly describes this detector and compares it with more conventional CCDs.

Most conventional CCDs use a floating diffusion amplifier (FDA) to read out the signal charge. The readnoise of the FDA has improved from several hundred electrons (rms) in the 1970s to less than 3 electrons in the last few years [3]. The energy resolution of CCDs over the entire soft x-ray bandpass is now limited by factors other than readnoise. It is desirable to push the readnoise down from a few
electrons to a fraction of an electron because it allows photons of lower energy to be detected in single-photon counting mode.

One method to further reduce the readnoise is to read out the same charge packet multiple times. The signal charge is destroyed when read out through an FDA. In the FGA, however, an insulating gate is placed between the charge transfer channel and the output node. Gates around the output node are used to read out and withdraw the signal charge multiple times. The readnoise is then reduced by the square root of the number of readouts. Effective readnoises of less than 1 electron have been demonstrated using the FGA [2,4], and photons of energy 66 eV (Al Lα) have been detected using the TGCCD. If the readnoise could be pushed to a fraction of an electron, it would be possible to detect optical photons in the single-photon counting mode.

Lower Readnoise
The other novel feature of the TGCCD is its electrode structure designed to maximize soft x-ray QE. Most conventional front-side illuminated CCDs have several hundred nanometers of SiO₂/Si₃N₄ insulator and Si electrode on the surface. These layers strongly limit the quantum efficiency of the device below 1 keV, but Fano-limited energy resolution is routinely achieved. The conventional solution to increase the low-energy QE has been to etch away the back surface of the device and illuminate it from behind (a back-side illuminated CCD). The difficulty with this technique is that the energy resolution is seriously degraded due to charge diffusion and poor charge collection.

The thin gate CCD is a front-side illuminated device with a unique gate structure that gives reasonable soft x-ray QE (0.20 at 277 eV), while retaining the good energy resolution of front-side illumination. The detector is a three-phase CCD. The first two phases (comprising only 1/3 of the active area of the device) are covered with 400 nm of polysilicon (or just poly) in the usual way. A third layer of poly is deposited on top of the first two and acts as a bus for a fourth (40-nm thick) layer of poly that defines the third clock phase. Two-thirds of the active area of the detector is therefore covered with only the insulator (100 nm of SiO₂ and Si₃N₄) and this fourth layer of poly. The measured energy resolution of this device is 34 eV at C Kα (277 eV). This is approximately a factor of 3 better than the best energy resolution obtained with the ACIS back-side illuminated CCDs [5]. Simulations show that an astrophysical spectrum obtained with TGCCD contains as much or more information than one obtained with a back-side illuminated CCD [6].

Radiation Damage
CCDs are often used in environments in which they are subject to ionizing radiation, and this radiation can degrade their performance. In particular, radiation damage plays an important role in the performance of most space-borne detectors. The Van Allen belts contain protons and electrons with energies of tens of MeV. These particles can produce damage by several mechanisms. Protons can generate vacancy-interstitial pairs in the Si lattice, which diffuse freely, even at cryogenic temperatures, and it is possible for the vacancy to form a complex with P atoms in the n-Si buried channel that traps electrons. The trap reduces CTE by preventing signal electrons from leaving the pixel during the clocking cycle. Electrons can also produce vacancies (although with much lower cross-section than the protons), but they can also create dangling bonds at the SiO₂–Si interface above the buried channel, leading to a shift in operating voltage in the CCD and contributing to noise.

The P–V complexes remove electrons from a charge packet in the conduction band of silicon. In the worst-case limit, when the illumination levels are so low that each charge packet transferred encounters each trap in its empty trap state, the degradation of CTE is approximately 5 × 10⁻² rad⁻¹ (radiation doses are expressed here in total ionizing rads in Si, although it should be noted that the fraction of proton energy that goes into production of vacancy-interstitial pairs, the nonionizing energy loss, is about 1/2000 of the total ionizing dose [17].) This degradation is significant: if the device is subjected to 1000 rad yr⁻¹ and there are 1000 transfers necessary to clock out the charge, then 40% of the charge packet would be lost due to proton-induced defects. At higher illumination levels, the traps greatly complicate the device response, particularly in single-photon counting applications. In this case, for example, the spectral response of the CCD becomes a function of the spatial distribution of the incident radiation.
This loss of CTE can be circumvented in several ways, including the use of increased shielding, a fat zero, annealing out the damage, implanting a narrow trough along the direction of transfer in the buried channel, or operating the device at a different (generally lower) temperature.

Relatively thick shielding, up to the equivalent 4 to 5 cm (1.6 to 2 inch) of aluminum, can provide significant attenuation (factors of several) of proton dose encountered in the radiation belts [18]. A fat zero is a uniform charge added to all the pixels of the CCD, usually induced by flooding the CCD with a low light level. Although a fat zero can reduce the CTE loss by filling the traps so they cannot be occupied by electrons from the charge packet of interest, they also add to the noise of the system. The P–V complex will dissociate at temperatures around 135° C [19], but the annealing is incomplete and may interfere with other requirements or constraints of the satellite mission. Using photolithography, a narrow trough or notch can be included in the buried channel parallel to the direction of transfer during fabrication, so charge packets are kept constrained and are less likely to interact with traps generated randomly across the buried channel [20]. It is not difficult to introduce a channel that is approximately 2 µm wide and can handle a charge packet of tens of thousands of electrons; this can decrease the CTE loss to $7 \times 10^{-8}$ rad$^{-1}$ or less. Reducing the operating temperature slows the kinetics of trap emptying [21], so a single electron can be lost from the charge packet and fill the trap for the integration time of the frame. The effectiveness of this process depends on the clock speed and integration time, as well as the ability to operate the CCD at temperatures that approach –150° C, but CTE loss can be as low as $10^{-8}$ rad$^{-1}$ if troughs are included with low-temperature operation. Cosmic rays and electrons can also cause damage by displacing Si atoms from the lattice, but the flux of cosmic rays is much lower than protons in low Earth orbits and the electrons are much less effective in creating a vacancy. The approaches to hardening against proton damage will also be effective with these latter two particles.

The major effect of electrons on CCDs is to shift the flatband voltage of the CCDs and MOSFETs, but for doses around 1000 rads, this change is on the order of 10 mV. If further hardening of the gate oxide is desired, it can be accomplished using established methods [22]. The passage of electrons and other energetic charged particles through a device also creates free carriers that constitute an interfering signal. One electron-hole pair is created for each 3.65 eV absorbed in the Si, and charged particles can deposit charge packets of up to a full-well level and more, depending on the species, energy, and the active depth of the device. In astronomy, such events are an annoyance, even in terrestrial observatories, and are removed by comparing images of the same scene. In some applications, such as x-ray spectroscopy, these events are more serious because they can masquerade as desired signals unless careful analysis of the data is performed to exclude them. On the other hand, this sensitivity to charged particles can actually be used to advantage. The known conversion between particle energy deposition and liberated charge means that CCDs can be used as spectroscopic detectors, and such an application has been proposed for inertial-confinement fusion diagnostics [23].

Radiation hardening of CCDs has made rapid progress in the last few years, allowing devices to have much longer lives for scientific applications. Fabrication and operational changes have increased the hardness to displacement damage and the process requirements of high-quality ICs have led to a gate dielectric that is quite robust to ionizing radiation.

57.1 Introduction

As the name indicates, densitometry is the measurement of optical density (O.D.). Optical density, in turn, can be broadly defined as a measure of the attenuation of radiant flux by some sort of optical element that can be transmitting, reflecting, or both. Densitometry is most widely applied in photographic science, and measurements in this field are covered by a four-part ANSI/ISO standard [1]. The treatment here follows that document. The measurement of transmission and reflection from the standpoint of optics has been discussed by Palmer [2]. This chapter uses the single word density, without the adjective, and uses the words “light” and “flux” interchangeably (although density can be measured in the UV and IR also, of course).

It turns out that, in practice, the measured density of a given sample can be affected significantly both by the design of the equipment and the nature of the sample. Therefore, the first rule of practical densitometry is that the sample must be measured in a way that is meaningful with respect to its intended use.

57.2 Monochrome Transmission Density

It is convenient to start by discussing transmitting samples, without the color aspect. Such samples can be either black-and-white photographic films or filter layers of various sorts. If light falls on such an element, a fraction of the flux is reflected from the first surface. The remainder penetrates the surface, and a part of this flux is absorbed. What is neither reflected nor absorbed exits the layer, as shown in Figure 57.1. Let these fractions be denoted, \( r, a, \) and \( t \), where lower-case \( t \) indicates internal transmittance. If the element is in air, reflection can occur at the rear surface also, but this can be neglected. By the conservation of energy, one obtains

\[
r + a + t = 1
\]  

(57.1)
The fractions $r$ and $t$ can be measured independently by spectrophotographic techniques, so that $a$ is readily determined. This fraction is termed the absorbance of the layer, and its measurement is also discussed by Palmer [2].

Some applications require the measurement of absorbance, but in most practical work, what is important is the fraction of the incident light that exits the element, regardless of where attenuation takes place. Therefore, transmittance is defined by:

$$T = \frac{\Phi_e}{\Phi_i} \quad (57.2)$$

where $e$ and $i$ refer to emergent and incident flux, respectively. Note that all losses are lumped together. In silver halide photographic layers, the first-surface reflection is usually small; in thin-film filters, a significant proportion of the total loss may occur by reflection. Following Hurter and Driffield [3], the English pioneers of densitometry, one can define the transmission density $D$

$$D = -\log_{10} T = \log_{10} \frac{1}{T} \quad (57.3)$$

Density is therefore a nonlinear dimensionless quantity $\geq 0$. McCamy has published an extensive review of densitometry and sensitometry [4].

The operation of a practical densitometer can be discussed with reference to Figure 57.2. The system consists of a light source, an aperture to define the area being measured, a sensor, logging circuitry, and a suitable readout display. In many instruments, the output is fed to a computer.

FIGURE 57.1 Cross-section of emulsion layer showing (A) reflection, (B) absorption, (C), diffuse transmission, and (D) specular transmission.

FIGURE 57.2 Schematic of transmission densitometer.
To measure transmittance/density, a reading is first taken with no sample over the aperture. This reading is a measure of the incoming light $\Phi_i$. A second reading with the sample in place then determines $\Phi_e$. It should be clearly understood that what the system actually does is to sense the flux passing through the aperture in the two cases, and then displays the negative logarithm of the ratio. This fact explains some of its operating characteristics. Starting from this basis, for example, McCamy [5] has treated measurement errors for the case when the sample is not uniform (“wedged”) over the aperture.

The basic procedure also means that any source having enough power to operate the sensor can be used, and filters and apertures can readily be interchanged; it is only necessary to “zero” the instrument before making a measurement. The measuring aperture is usually of the order of 1 mm in diameter. If the area of this aperture is reduced to, say, 0.1 mm$^2$, the device becomes a microdensitometer. Such instruments present special problems not discussed here but treated in the literature [6].

Now consider the complications introduced by the nature of samples, especially photographic samples. Developed black-and-white photographic layers consist of discrete grains of silver metal dispersed in a thin layer of gelatin. Such grains act as scatterers, which means that some of the photons exiting the layer will not be traveling in their original directions. Such photons are identified by “C” in Figure 57.1. Clearly, the measured transmittance/density will depend on how much of this scattered light reaches the sensor. The effect of scattering can be quite large, and therefore in order to obtain values that are both reproducible and meaningful it is necessary to control what is termed the “geometry” of the system, i.e., the angular subtenses of the influx and efflux beams at the sample.

In Figure 57.3, $\Theta_i$ and $\Theta_e$ are these half-angles, respectively, referred to the normal to the element surface. The current standard [1b] prescribes two configurations, the first of which is as follows: $\Theta_i = 5^\circ; \Theta_e = 90^\circ$. The reverse of this configuration, i.e. $\Theta_i = 90^\circ; \Theta_e \leq 5^\circ$, yields the same density readings and is also permitted by the standard. This case is termed “diffuse density” and is the most important practical case because most commercial densitometers conform to this mode. Essentially, all the light exiting the sample, whatever its direction, reaches the sensor and is evaluated. This configuration simulates the case of contact printing a photographic negative, or of viewing a transparency on a diffuse illuminator. The practical construction of such an instrument is described below.

The second case occurs when the sample is illuminated, and the emergent flux collected, by lenses of finite aperture. In principle, in this case, the angles $\Theta_i$ and $\Theta_e$ can vary between, say, 5$^\circ$ and 90$^\circ$ and may differ from one another, but the standard specifies two sets of optics with matched apertures of $f/1.6$ and $f/4.5$. These relative apertures are representative of motion picture projectors and microfilm readers, respectively. The corresponding half-angles are 18.2$^\circ$ and 6.4$^\circ$. (For a lens in air, $f$/no. = 1/(2sin$\Theta$), where $\Theta$ is the half-angle shown in Figure 57.3.) This case is termed “projection” density.

It is useful to define a ratio

$$Q' = \text{Projection density/diffuse density} \quad (57.4)$$

![Figure 57.3](image-url) Angular subtenses of influx and efflux beams at sample.
which has been termed the “effective Callier coefficient.” As would be expected, projection density is greater than diffuse density for a given sample so that $Q' = 1$. The exact ratio between the two densities depends on the scattering characteristics of the sample and the $f$-numbers involved. Only limited information on $Q'$ has appeared in the literature [7] but, as Figure 57.4 shows, this parameter behaves as might be expected.

The dependence of the effective density on aperture shown in Figure 57.4 may be important in practice. Amateur photographers are aware that a B&W negative usually produces a more contrasty print in a condenser enlarger than it does in a diffuser enlarger, and this behavior can easily be deduced from Eq. (57.4). It may also be important in microdensitometry, since these instruments measure a projection density and a wide range of apertures may be encountered in various instruments. In such cases it is usually recommended that the data be reduced to diffuse density. This is easily done by measuring a sufficiently large sample in both projection and diffuse densitometers. It might be remarked that the scattering characteristics of individual films can vary significantly, and $Q'$ should be measured for the samples at hand. Except for very low densities, $Q'$ is relatively unchanged as the diffuse density varies.

For completeness, it is noted that earlier editions of density standards listed two other forms of density. The first of these was the case of angle $\Theta_i = \Theta_e \leq 5^\circ$. This case was termed “specular density” and was intended to simulate the use of the attenuating element in a collimated beam. The second case was the case of angle $\Theta_i = \Theta_e = 90^\circ$. This type of density was termed “doubly diffuse,” and was intended to simulate the use of a negative in certain contact printers. Neither of these densities is important in modern practice; discussions of them can be found in the literature [8].

In a color film, the “grains” are actually tiny volumes of dyed gelatin. Since the index of refraction of such a “grain” is only slightly different from the surround, it does not act as a scatterer. Thus, the density differences found on color films as a function of densitometer geometry are usually negligible and often ignored in practice.

In recent years, the photographic industry has introduced a new type of grain, the “tabular” grain, whose thickness is much smaller than the dimensions in the plane parallel to the coating surface. It has been demonstrated that, in the undeveloped state, these grains scatter light significantly less than the older “3-D” types of grains. No studies of developed T-grains have appeared in the literature, but it seems possible that developed B&W layers consisting of T-grains may scatter less than the traditional types of layers, thus reducing the sensitivity of density measurement to instrument geometry. (The data of Figure 57.4 were obtained with “3-D” grains.)

One can now turn to the optical configuration of a practical diffuse densitometer. From an optical standpoint, a good way to collect all the flux exiting the sample would be to use an integrating sphere,

![Figure 57.4](image)

**Figure 57.4** Variation of the effective Callier $Q'$-factor with the $f$-numbers of the influx and efflux beams, which were matched.
and instruments have been built using such spheres. However, in an actual contact-printing case there will be some light reflected back to the negative from the paper surface. Any retroreflection from an integrating sphere will of course be quite different from that coming from a paper surface. The better to simulate the contact-printing case, the present ANSI/ISO standard specifies that, in diffuse densitometers, the emulsion side of the sample shall be in contact with opal glass, which both acts as the diffuser and provides the desired back reflection. The optics of a diffuse densitometer are shown in Figure 57.5.

In the system shown, the sample is illuminated by diffuse light, which is the reverse of what is shown in Figure 57.3; however, as noted, diffuse density optics are reversible. Weaver studied the differences between opal-glass and integrating-sphere densities and found that because of the interreflections, the values were slightly lower in the opal-glass case [9]. The difference was \( \sim 0.04 \) density unit for very low densities, decreasing to 0.01 to 0.02 for samples whose densities were between 2.0 and 3.0. The opal-glass construction was also adopted in the standard because such instruments are easier to build and maintain. Care must be taken, however, to ensure that the diffuser meets the standard’s specifications.

In actual operations, it is too time-consuming to zero the instrument before each reading. Likewise, the fraction \( \Phi_r/\Phi_i \) is rarely calculated specifically; the instrument simply provides a reading based on the amount of flux reaching the sensor. Because of the possibility of electronic drift however, it is advisable to zero the instrument periodically, unless it is known to be dependably stable. Likewise, the readings produced for some accurately known calibration sample of high density should be checked, a procedure known as “sloping” the instrument. Standard samples are available for this purpose; see the Appendix.

### 57.3 Monochrome Reflection Density

By definition, the reflectance factor

\[
R = \frac{\Phi_r}{\Phi_o}
\]  

(57.5)

where \( \Phi_r \) is the flux returned to the sensor from the sample, and \( \Phi_o \) is the flux returned by a “perfectly reflecting, perfectly diffusing material located in place of the specimen” [1d]. Reflection density is then

\[
D_R = -\log_{10}R = \log_{10}\frac{1}{R}
\]  

(57.6)

The optical configuration specified in the standard is shown in Figure 57.6. With reference to the normal to the specimen surface, one beam subtends an angle of \( 0 \pm 5^\circ \) and the other an angle of \( 45^\circ \pm 5^\circ \). Also, the \( 45^\circ \) beam is annular. As in the case of transmission optics, the influx and efflux beams are interchangeable. When the influx beam is at \( 45^\circ \), the system is termed “45/0”; when the efflux beam is at \( 45^\circ \), the designation is “0/45.” The angle between the two beams was selected to avoid the specular reflection from the surface. The \( 45^\circ \) beam is made annular to minimize the effects of any texture pattern that might be embossed on the sample surface. The standard also specifies that when measured, samples
shall be backed by a black diffusing material having a reflection density not less than 1.5. This procedure is specified to improve reproducibility, especially for thin samples.

It will be obvious that a reflection densitometer cannot be “zeroed” by taking a reading with no sample in place. Instead, as prescribed by the Standard [1d], calibration samples that have been measured on other primary instruments are used both to zero and slope the densitometer. Formerly, coatings of MgO$_2$ or BaSO$_4$ were used as reference “whites,” but these layers are difficult to use. An ASTM standard [10] discusses the preparation of reference whites from pressed powders. For routine work, “plaques” consisting of stove enamel of various gray levels on a metal substrate are widely used. These plaques are very durable, but their physical form is quite different from actual paper samples. Photographic paper strips that have been calibrated in primary instruments can also be used. Physically, these strips are exactly like the samples to be read, but they are very easily damaged and must be used with care. Any scratch in the surface can cause a specular reflection to reach the sensor, which will produce a false reading.

Actually, the reflection of light from a photographic paper is more complicated than might appear at first glance. A typical B&W paper is shown in cross section in Figure 57.7. As with film samples, the emulsion layer consists of Ag grains suspended in gelatin. The support is a diffuse reflector. It turns out that reflection to the sensor occurs in three ways, as sketched. (The specular reflection is omitted in Figure 57.7.) Note that the component $r_2$ traverses the emulsion layer twice and $r_3$ at least four times, and that $r_1$ does not traverse the layer. For low densities, all three components contribute to the reflection reading. As the population of grains in the emulsion layer grows, the multiply-reflected beam $r_3$ rapidly becomes negligible. With continued increases in the grain population, the component $r_2$ also reduces to insignificance, and only the $r_1$ component remains. This component, being a surface reflection, remains essentially constant at about $0.005I_0$.

The mechanism described above can be confirmed by measuring the densities of a test strip by transmission and then cementing the strip to a diffuse reflector and measuring the same densities by reflection. The results of such an experiment are shown in Figure 57.8. This curve has three regions, as expected. In the first region, the slope is greater than 2, corresponding to the rapid loss of the $r_3$ component. In region $2$, $\Delta D_b = 2\Delta D_{t_3}$; in this region, most of the photons reaching the sensor are those that have traversed the layer twice. Finally, in the third region of the curve, the $r_3$ component has become negligible, and only the surface component $r_1$ remains significant. Since, as noted, this component $\sim 0.005I_0$, the maximum reflection density attainable in a photographic paper should be about 2.0 to 2.3.
and this is found to be the case for actual papers. (We have assumed a glossy paper. If the paper surface is textured, as it is in some products, specular reflections may be directed to the sensor from microareas and the maximum density attainable on the sample will drop, in some cases significantly.) The curve of Figure 57.8 also becomes very important in color reflection work, as is discussed below.

## 57.4 Color Transmission Densitometry

So far, we have assumed either that the measuring beam was monochromatic or that the sample was neutral, i.e., that transmittance or reflectance was constant across the spectrum of interest. Actually, the assumption of neutrality is reasonable for many B&W materials. However, of course, the densitometry of color images is extremely important, and this aspect is discussed below.
Before doing so, however, it will be useful to make a brief digression into the structure of photographic color materials [11]. Although an oversimplification, we can consider such materials to be three separate films coated one over the other on a single support. From the top down, the spectral sensitivities of these three layers are adjusted to record the blue, green, and red regions of the visible spectrum, respectively. In accordance with the principles of subtractive color reproduction, the images recorded in these layers are formed of yellow, magenta, and cyan dyes (again from the top down). The problem is to densitometer these dyes. As before, we start with transmitting samples. Referring back to Figure 57.2, for any wavelength $\lambda$, the reading of the instrument with no sample in place will be

$$KS_{\lambda}s_{\lambda}F_{\lambda} = KJ_{\lambda}$$ (57.7)

where $K = $ proportionality constant, $S_{\lambda} = $ spectral power of the influx beam at $\lambda$, $s_{\lambda} = $ relative spectral sensitivity of the receiver at $\lambda$, and $F_{\lambda} = $ transmittance of any filters in the beam at $\lambda$. (The transmission of the instrument optics may be significant, but this can be included with $S_{\lambda}$, since it is a fixed characteristic of the device.) The product $J$ is termed the “response” or the “spectral product” of the instrument.

If a sample whose transmission at wavelength $\lambda$ is $T_{\lambda}$ is now placed over the aperture, the reading will be

$$KS_{\lambda}s_{\lambda}F_{\lambda}T_{\lambda} = KJ_{\lambda}T_{\lambda}$$ (57.8)

and the measured transmittance reduces to $T_{\lambda}$, as it should. Thus, in the monochromatic case, the measured value is independent of the system response. When the influx beam contains two discrete wavelengths, the no-sample reading becomes

$$K(J_1 + J_2)$$ (57.9)

and with the sample in place it will be

$$K(J_1T_1 + J_2T_2)$$ (57.10)

The measured transmittance

$$T = \frac{J_1T_1 + J_2T_2}{J_1 + J_2}$$ (57.11)

Note that when the sample is neutral, Equation 57.11 again reduces to the case where the transmittance is independent of the instrument response. But when the sample is not neutral, Equation 57.11 can no longer be simplified. In other words, in the general case the transmittance/density values depend on the system response as well as on the sample.

For continuous bands of radiation, Eq.(9) becomes

$$T = \frac{\int J_\lambda T_\lambda d\lambda}{\int J_\lambda d\lambda}$$ (57.12)

and

$$D = -\log_{10}\left[\frac{\int J_\lambda T_\lambda d\lambda}{\int J_\lambda d\lambda}\right] = \log_{10}\left[\frac{\int J_\lambda d\lambda}{\int J_\lambda T_\lambda d\lambda}\right]$$ (57.13)

The integration limits are set by the distributions.
From the above analysis, it is clear that in order to obtain meaningful density values, the spectral characteristics of the densitometer must be made equal to those of the receiver that will “view” the sample in actual use. Furthermore, of course, the actual receiver will vary from application to application. The densitometer characteristics are set by inserting appropriate filters in the beam. A number of spectral distributions are specified in Reference 1c as follows:

1. For reflection densitometry, the influx spectrum shall be ICI Illuminant A, which is essentially 2856 K.
2. For transmission densitometry the influx spectrum shall be Illuminant A modified by an infrared absorbing filter, as tabulated in the standard.
3. For samples to be viewed by an observer, the spectral characteristic of the system shall match the relative luminosity function \( V(\lambda) \). This case is termed “visual” density.
4. For color negative films, a set of three distributions in the red, green, and blue regions of the spectrum is specified. This set is identified Status M, and approximates the spectral sensitivities of the three layers of color print materials.
5. For measuring red, blue, and green densities of color materials other than color negatives, a set of three responses identified Status A is provided.
6. To evaluate color images to be used in graphic arts processes, two sets of distributions are specified and are identified as Status T and Status E.
7. In the microfilm industry, prints are often made onto diazo or vesicular films. A narrow distribution centered at 400 nm is specified for this application, and the resulting densities are termed ISO printing densities Type 1.
8. A spectral distribution covering the range \( \lambda \approx 360 \) to 540 nm is provided for measuring samples to be printed onto B&W photographic papers. Such densities are designated ISO printing densities Type 2.
9. Status I response consists of three passbands centered at 420, 535, and 625 nm ±5 nm. This set is used in evaluating graphic arts materials such as process inks on paper.
10. A narrowband response centered at 800 nm ± 20 nm is provided for measuring effective densities to S-1 photosurfaces, such as those used in optical sound systems. Densities measured with this response are identified “ISO type 3.”

These responses are shown in Figures 57.9a–e, which are reproduced from the current standard.

The next problem in color densitometry stems from the fact that the three layers are superimposed and from the nature of the dyes. The spectrophotometer curves for a typical dye set are shown in Figure 57.10. In this figure, the lower three curves refer to the dyes measured individually, while the upper curve shows the result of superimposing them. The values for the individual dyes are termed “spectral analytical densities,” and those for the tri-pack are termed “spectral integral densities.” Since superimposed densities may be considered to add, at any wavelength the spectral integral value is the sum of the three analytical values. Note that all three of the individual dyes absorb light outside the spectral regions in which they are supposed to work.

This unwanted absorption can cause problems in color reproduction and, more to the point for this chapter, in densitometry, because straightforward measurements of a real film at any wavelengths yield integral values. In many cases, these integral values are required. In the manufacture and processing of films, however, it may become necessary to determine the densities in an individual layer. It is not sufficient to coat and measure a layer by itself, since layers coated in a tri-pack may respond differently from the same layers operated singly.

This problem is solved by taking advantage of two rules called the “additivity rule” and the “proportionality rule.” The first of these is merely the rule that densities add. The proportionality rule is an extension of Beer’s law. Consider an element, such as a glass cell or a layer of a color film, containing a dye whose concentration can be varied. Beer’s law states that
where $c$ is the dye concentration and $\beta_l$ is the extinction coefficient at wavelength $\lambda$. The coefficient $\beta$ varies with wavelength, of course, but will be constant at a given wavelength (unless changes in dye concentration produce chemical reactions.) Strictly speaking, Beer’s law applies to the internal transmittance, but in the case of photographic layers, the surface reflectance is negligible. From Equation 57.14, it follows that

$$T_{\lambda} = e^{-\beta_{\lambda}c}$$  \hspace{1cm} (57.14)

and therefore,

$$\ln T_{\lambda} = -\beta_{\lambda}c$$  \hspace{1cm} (57.15)

$$D_{\lambda} = 0.434\beta_{\lambda}c$$  \hspace{1cm} (57.16)

Consider now the density at two wavelengths for any given dye sample. Clearly,

$$\frac{D_{\lambda_1}}{D_{\lambda_2}} = \frac{\beta_{\lambda_1}}{\beta_{\lambda_2}}$$  \hspace{1cm} (57.17)
FIGURE 57.9b Spectral products for type 1 and 2 densities. (continues)

FIGURE 57.9c Spectral products for Status A and M densities. (continues)
FIGURE 57.9d Spectral products for Status T densities. (continues)

FIGURE 57.9e Spectral products for Status E and I densities.
Thus, for a given dye sample, the ratio of the densities at any two wavelengths is fixed regardless of dye concentration (i.e., assuming Beer’s law holds), and this is a statement of the proportionality rule.

As noted, straightforward density measurements on a real sample yield integral densities. The proportionality rule can be used to derive analytical densities in the following manner [12]. Assume spectral densities for simplicity. With reference to Figure 57.10, we select three wavelengths at or near the peak absorptances of the three dyes. Consider first the blue wavelength. By the additivity rule, the blue integral density is

\[ D_b = Y_b + M_b + C_b \]  

(57.18)

where \( Y_b \), \( M_b \), and \( C_b \) are the blue analytical densities of the yellow, magenta, and cyan dyes, respectively. But by the proportionality rule, \( M_b/M_g = \text{constant} \), where \( M_g \) is the analytical density of the magenta dye measured at the peak wavelength in the green. The value of this ratio is readily determined from a spectrophotometric curve of the dye. Denoting such ratios \( a_n \), for measurements at the three peak wavelengths we have

\[ D_b = Y_b + a_1 M_g + a_2 C_r \]
\[ D_g = a_3 Y_b + M_g + a_4 C_r \]
\[ D_r = a_5 Y_b + a_6 M_g + C_r \]  

(57.19)

This constitutes a set of three equations with three unknowns. The solution has the form

\[ Y_b = b_1 D_b + b_2 D_g + b_3 D_r \]
\[ M_g = b_4 D_b + b_5 D_g + b_6 D_r \]
\[ C_r = b_7 D_b + b_8 D_g + b_9 D_r \]  

(57.20)

**FIGURE 57.10** Spectral density distributions of the C, M, and Y components as functions of wavelength for a hypothetical color film, and of the composite absorber (N).
where \( Y_b, M_g, \) and \( C_r \) are the desired values of the three analytical densities. The \( b \)-coefficients are algebraic combinations of the \( a \)-coefficients, which can be reduced to numerical values since the \( a \)-coefficients are known. In practical work, the determination of the \( a \)-coefficients is usually done using data for a number of different dye density levels. The off-peak density for each level is plotted against the peak density, giving a straight line whose slope is a good measure of the \( a \)-coefficient. Thus, for example, the coefficient \( a_i \) in Equation 57.14 would be found by plotting \( M_b \) vs. \( M_g \) for several levels. The values of the coefficients can also be found by doing narrow-band densitometry on the samples instead of spectrophotometry.

So far, we have been assuming spectral densities. By the first law of densitometry, however, any sample should be measured with a system whose spectral response is equal to that used in actual practice—in other words, color negative samples should be measured with the Status M filters described before, etc. However, the analysis described above works satisfactorily with the status filters, which are relatively narrow-band, and much practical densitometry is performed in this manner.

Finally, because of its practical importance, we must introduce one more type of color density: the “equivalent neutral density,” or END. END is defined as the neutral density that a given dye deposit—either yellow, magenta, or cyan—will produce when it is combined with the correct amounts of the other two dyes, whatever those amounts may be. It is important in practical film building, because one of the most important properties of a color film is its ability to produce a neutral as a neutral—in other words, to image a gray object as a gray that shows no residual tint of another color. Such a film is said to be “balanced,” and good balance is considered extremely important by discriminating users. When the ENDS of the three layers of a color film are equal, the image will indeed be balanced, and color film sensitometry may be done in terms of ENDS. The END is a form of analytical density because it is a property of an individual layer. Originally, ENDS were measured in a special densitometer, but they are now calculated from the normal analytical densities by an equation of the form

\[
\text{END} = m[\text{analytical spectral density}] + K \tag{57.21}
\]

where the constants \( m \) and \( K \) are determined by comparing the visual densities of satisfactory neutral images with the corresponding analytical spectral densities. In some cases, a second-order equation has been found to yield better results [12b].

### 57.5 Color Reflection Densitometry

Color reflection densitometry follows the general principles set forth above for the B&W reflection case. Since color prints are for the most part intended to be viewed by a human observer, in many cases a visual integral density provides the needed information. The film builder or process controller, however, may need information about the analytical densities of his layers, and here the approach used for transmitting samples does not work. The reason it fails is that, for such samples, Beer’s law fails, as is shown by the curve of Figure 57.8. If the law held, the reflection density would be proportional to the dye concentration (see Equation 57.11).

Pinney and Vogelsong [13] have described a method of obtaining reflection analytical densities in such cases. The method involves the empirical determination of a calibration curve similar to Figure 57.8 for the material at hand, relating the reflection densities of a dye deposit to the transmission densities. The reflection integral densities of the sample are then measured and converted to transmission densities. The analytical values for these transmission densities are calculated using the method described above for such samples. Finally, the derived transmission values are converted back to reflection analyticals by going through the calibration curve in the reverse direction.

One last comment on the densitometry of color print papers should be added. In the commercial production of color prints, it may be extremely important to measure chemical stain in what should be the white areas of the picture. The passbands of the Status A filters are not well placed to monitor such stain, and it may be necessary to make additional measurements.
57.6 Densitometry of Halftone Patterns

Halftone patterns are used in the printing industry to reproduce continuous-tone images using two levels of ink: either ink or no ink. Various gray levels are produced by printing a pattern of repetitive “dots” too small to be resolved by the unaided eye. Essentially, the size of the dots is varied to produce a gray scale. Halftone patterns to be measured may be transmitting or reflecting; monochrome or color. A number of standards for densitometry in the graphic arts have been approved or are under development [14]. These standards provide much practical guidance, and are consistent with ISO-5. Densitometry in this field is an example of the basic mechanism by which the instrument operates—comparing the flux reaching the sensor with and without the sample in place. When the sample is a halftone, the flux reaching the sensor depends on the fractions of the area that are dense and clear. Adopting the notation of Ref. 13b and assuming a transmitting sample, the measured density will be

\[
D_t = -\log_{10} T = -\log_{10} [f T_s + (1 - f) T_b] \tag{57.22}
\]

where \(D_t\) = measured density of pattern, \(T\) = average pattern transmittance, \(f\) = fraction of pattern area that is dense, \(T_s\) = transmittance of “solid” areas (essentially equal to dot density), and \(T_b\) = transmittance of clear areas.

It is interesting to calculate the measured density of a halftone pattern half of which is perfectly dense \((D = \infty; T = 0)\) and half of which is perfectly clear \((D = 0; T = 1)\). The calculated value for \(D = 0.3\) and this value will indeed be found if such a pattern is densitometered.

If \(D_o\), \(T_s\), and \(T_b\) are known, Equation 57.22 provides an easy way to determine the fractional area covered by the pattern dots with an ordinary densitometer, and this is often done in graphic arts work. In practical work, \(T_s\) and \(T_b\) are measured in terms of density also, and this can be done satisfactorily on large areas. Since by definition \(T = 10^{-D}\), the solution of Equation 57.22 for \(f\) can be written

\[
f = \frac{1 - 10^{-D}}{1 - 10^{-D_o}} \tag{57.23}
\]

In this form, the equation is known as the Murray-Davies equation.

57.7 Summary

A densitometer measures the flux reaching the sensor with a sample in place, and calculates the ratio of this value to that obtained either with no sample in place (in the transmission case) or with a reference white in place (in the reflection case). The instrument then displays the negative log of this value.

The observed reading may depend significantly on the characteristics of the instrument, i.e., on the

1. angular substance of the influx beam,
2. angular substance of the efflux beam,
3. spectral power distribution of the influx beam, and
4. spectral sensitivity of the receiver.

For a complete specification of the density in a given case, these four parameters should be indicated. ISO 5.1. (Ref.1a) provides a standardized notation.

58.1 Introduction

Imagine how dull a world without color would be. Until the 1960s, many products were available in only a limited variety of colors. Consumers demand a variety of colors, and the materials available today allow manufacturers to meet those demands.

For many centuries, color was controlled by master color matchers adjusting the color of their products visually in natural daylight. It was about the 1950s when color measuring instruments began to make a significant impact in the manufacturing process, and by the 1970s they were commonly used in most industries. Color measuring instruments are used mostly for quality control but also for computerized color matching systems, process control, evaluation of raw materials, and as an aid to solving color problems.

While it is common to speak of a red car or a red light, color is a perception—not an intrinsic property of the object or the light. Color perception is influenced by the light source, the reflectance or transmittance properties of the object, the eye, and the brain. Color is one aspect of appearance. Gloss and texture are other aspects.
Color perception is three dimensional, i.e., three terms are needed to describe a color. Hue, lightness (sometimes called value), and chroma are one set of terms often used to describe color. Hue distinguishes blue from green from yellow, etc. Lightness distinguishes light colors from dark colors—for example, a light blue fabric from a dark blue fabric. Chroma, the most difficult of the three terms to understand, describes how different a color is from gray—for example, distinguishing a pastel green from a bright green. If the two greens are of the same hue (one is neither yellower nor bluer than the other) and have the same lightness, then the pastel green would be described as having a low chroma and the bright green as having a high chroma. Figure 58.1 is a diagram illustrating the three dimensions of color.

Daylight, fluorescent lamps, and incandescent lamps are widely used light sources for color evaluation. The perceived color of an object changes as the light changes. The human visual systems attempt to compensate for the change in light source and hold the color constant. Light booths provide standardized and controlled light sources for the visual evaluation of color. Most light booths contain a simulated daylight lamp, a cool white fluorescent lamp, an incandescent lamp, and an ultraviolet lamp for detecting fluorescence. By use of a switch, a light booth can be used to examine how the perception of a colored material changes with different light sources.

Two objects may appear the same when viewed under one light source, but different when viewed under another light source. This effect, called metamerism, is one of the major industrial problems for color matching. Metamerism usually occurs when attempts are made to produce objects that are the same color but made out of different materials, such as trying to match the dyed textile interior of a car with paint on the exterior and the plastic on the dashboard.

Colorimetry, the measurement of color, attempts to quantify the perception of color. The Commission Internationale de l’Éclairage (International Commission on Illumination, or CIE) is a voluntary organization of scientists and engineers from all over the world who are interested in light and color. The recommendations constituting modern colorimetry were first published by the CIE in 1931 and have been regularly updated since then [1].

Electromagnetic radiation (x-rays, gamma rays, light, and radio waves) irradiates the Earth constantly. Visible light is the name given to the electromagnetic radiation that the human eye perceives. The wavelength of visible light ranges from about 380 nm to about 780 nm. Sunlight is a mixture of all the wavelengths of light. Water vapor can spatially separate the light into its various wavelengths—the rainbow. Prisms and diffraction gratings can also spatially separate light into its component wavelengths.

![Figure 58.1: The three dimensions of color.](image-url)
Light sources can be described numerically by their spectral power distribution, the relative amount of power the source emits at each wavelength of interest. A light source may emit power at wavelengths below (ultraviolet “light”) or above (infrared “light”) those of visible light. Ultraviolet radiation is important to colorimetry because it can cause fluorescence. Infrared radiation is the basis of “heat lamps” but is not important in colorimetry. Spectroradiometers measure the spectral power distribution of light sources.

Illuminants and sources are sometimes confused. Sources are actual physical entities that produce visible radiation, whereas an illuminant may only be a numerical table of values of a spectral power distribution. Initially, the CIE recommended three light sources for colorimetry in 1931. Source A, which is still in use, is an incandescent, tungsten filament light. An illuminant is the spectral power distribution of a light source. Thus, Illuminant A is the spectral power distribution of Source A. An illuminant may be defined, even when a source for that illuminant does not exist. Examples of illuminants without sources are the D series of illuminants recommended by the CIE. The D illuminants represent various phases of daylight. Illuminant D65 represents average daylight and is the most common illuminant used in colorimetry. No sources were recommended for the D series of illuminants.

Fluorescent lights have great commercial importance. Cool white fluorescent lamps are the most common light sources in offices in the United States. There are a variety of other types of fluorescent lamps used in stores and offices. The CIE also recommended a series of illuminants to represent fluorescent lamps. F2 represents cool white fluorescent lamps. Figure 58.2 shows the spectral power distributions of Illuminants A, D65, and F2.

Color vision and perception is complex and has been extensively studied. Ninety-two percent of men and 99.5 percent of women have “normal” color vision. The eye’s lens focuses images on the light-sensitive retina. Rod cells make up the majority of the retina and are sensitive to low levels of illumination (night vision). Cone cells provide color vision and are located in a small area of the retina called the foveal pit. There are three types of cone cells. One type of cone cell has peak sensitivity to blue light, one type to green light, and one type to red light. Signals from the cone cells are transmitted to the brain where they are processed into color perceptions.

Color perception is an extremely complex phenomenon. For example, the background on which a material is viewed can have a major effect on the perceived color of that material. The ambient light to which the eye becomes adapted also influences the color of materials. Basic colorimetry, the topic of this chapter, provides the rather simple concept of dealing with the measurement of single independent colors. Most of industrial color control is adequately described using basic colorimetry. Advanced colorimetry attempts to use physical measurements to describe the perceived color of a material when viewed in a complex scene.

All colors are perceived by stimulating combinations of the three cones. Computer monitors and color television tubes produce colors by lighting combinations of red, green and blue phosphors. In 1931 when
the CIE was developing the system for modern colorimetry, they transformed the data from real experiments that had human observers match each wavelength of visible light with combinations of red, green and blue lights, to three mathematical imaginary “lights” labeled X, Y, and Z. All colors can be matched by varying amounts of X, Y, and Z. The amounts of each X, Y, and Z imaginary light that must be mixed together to match a color are called the tristimulus values (see “The CIE Standard Observers,” page 58-6).

Most objects absorb, transmit, or reflect (scatter) light. Transparent objects absorb and transmit light. Opaque objects absorb and reflect light. Light sources emit light. Fluorescent objects absorb, reflect, and emit light. Translucent or hazy objects absorb, transmit, and scatter light. Measuring the color of fluorescent, translucent, and hazy objects is difficult and will be covered in later sections.

Objects are characterized by the amount of light they reflect or transmit at each wavelength of interest. Most spectrophotometers measure reflectance factors rather than reflectance. Reflectance is the amount of light reflected from an object compared to the amount of light illuminating that object. The reflectance factor is the amount of light reflected from an object compared to the amount of light reflected from a perfect diffuser under the same conditions. A perfect diffuser is a theoretical material that diffusely reflects 100 percent of the light incident upon it. The term reflectance is often used in a general sense, or as an abbreviation for, reflectance factor. Such usage may be assumed unless the term reflectance is specifically required by the context [49]. Spectrophotometers designed for color measurement usually measure reflectance or transmittance at 10- or 20-nm intervals throughout the visible spectrum.

When the reflectance or transmittance of an object is low, the object absorbs most of the incident light; when it is high, the object reflects or transmits most of the incident light. Figure 58.3 shows the reflectance curve of a printed yellow ink. Note that the yellow ink absorbs light in the blue portion of the spectrum.
of the spectrum and reflects light in the yellow and red portions of the spectrum. A green plastic (Figure 58.4) absorbs light in the blue and red portions of the spectrum and transmits light in the green portion.

The tristimulus values of an object can be calculated by combining the reflectance or transmittance of the object with the spectral power distribution of an illuminant and the color matching functions of a Standard Observer. The yellow ink's tristimulus values for Illuminant D65 and the 10 Degree Standard Observer are \(X = 66.62\), \(Y = 69.72\), and \(Z = 7.03\). Those for the green plastic are \(X = 21.03\), \(Y = 39.40\), and \(Z = 24.06\). An object's tristimulus values will change with the illuminant. For example, the tristimulus values for the yellow object for Illuminant A and the 10 Degree Standard Observer are \(X = 91.15\), \(Y = 77.83\), and \(Z = 2.80\).

Pairs of objects are said to match when their tristimulus values are the same. However, since the calculation of the tristimulus values included the source and observer as well as the object, when one of these changes, the objects may no longer match, i.e., they may have different tristimulus values. Metameric colored objects have the same tristimulus values for the illuminant under which they match but different tristimulus values for illuminants where they do not match.

Color measurements are most often made to determine quantitatively whether or not the colors of two objects or batches of material are the same. But what happens when they do not match? Color difference equations were developed to quantify the difference. Starting with the objects' tristimulus values, a color difference equation will calculate the total color difference, \(\Delta E\) or \(DE\), and its component parts—the differences in lightness (\(\Delta L\) or \(DL\)), chroma (\(\Delta C\) or \(DC\)) and hue (\(\Delta H\) or \(DH\)) or the differences in lightness, yellowness-blueness (\(\Delta b\) or \(Db\)) and redness-greenness (\(\Delta a\) or \(Da\)). Numerical color differ-
ences may be used for setting tolerances for quality control applications, to answer the question: is the match close enough?

58.2 Standardized Light Sources

Color Temperature

Light sources may be described by their color temperature. A block of carbon would look completely black when its temperature was at absolute zero, 0 K. When the carbon block is heated to about 2850 K, it looks yellow—about the same color as an incandescent light bulb. Heat the block to 5000 K, and it looks whitish. At 7500 K, the block would have the bluish color of north sky daylight. A full (blackbody) radiator is a theoretically perfect emitter and absorber of radiation that changes color like the carbon block just described. The color temperature of a light source is the temperature of a full radiator that has the same color as the light source. When a light source does not exactly match the color of a full radiator, the correlated color temperature is used to describe the light source. The correlated color temperature is the temperature of a full radiator whose color is closest to the source.

Daylight varies during the day—redder in the morning and evening and bluer at noon. Average daylight (diffuse skylight without direct sunlight) has a color temperature of 6500 K. North sky daylight is preferred by many people for the visual evaluation of color and has a color temperature of 7500 K.

CIE Recommendations

Source A has a color temperature of 2856 K. The CIE recommended daylight illuminants are referred to by the prefix D, followed by the first two digits of their color temperature. Thus, CIE Illuminant D65 has a color temperature of 6500 K. Illuminant D50 has a color temperature of 5000 K and is preferred by the graphic arts community. Illuminant D75 would be used for north sky daylight having a color temperature of 7500 K. Illuminant F2 has a color temperature of about 4100 K.

58.3 The CIE Standard Observers

The CIE adopted two Standard Observers based on color matching experiments. The CIE 2 Degree Standard Observer was recommended in 1931, and the CIE 10 Degree Standard Observer was recommended in 1964.

In the CIE experiments, observers having normal color vision matched spectrum colors with combinations of red, green, and blue light. Figure 58.5 illustrates the experimental setup used in the Standard

![FIGURE 58.5 Experimental field of view for determining the CIE Standard Observers.](Image)
Observer experiments. One-half of a circular field was illuminated with the spectrum color, while the other half was illuminated with a mixture of red, green, and blue lights. The observer adjusted the amounts of red, green, and blue until the mixture matched the spectrum color. Unfortunately, not all of the spectrum colors could be matched with combinations of the red, green, and blue lights used in the experiment. In those cases, one of the lights had to be moved so that it illuminated the test field. By “diluting” the spectrum color with one of the lights, the resultant color could be matched with the remaining two lights. The amount of light used to dilute the spectrum color was considered to be a negative amount. To avoid having color matching functions with negative amounts of light, three “imaginary” lights (X, Y, and Z) were created by performing a mathematical transformation. Color matching functions are the amounts of X, Y, and Z required to match the colors of the spectrum and are used in the calculation of tristimulus values. Figure 58.6 shows the color matching functions, (\(x\), \(y\), and \(z\)) for the 10 Degree Standard Observer.

In the first experiments, the circular field viewed was projected on the foveal pit and subtended a solid angle of 2°. This is about the size of a dime held at arm’s length. The 2 Degree Standard Observer developed from these experiments is very useful when viewing small fields, such as the signal lights of ships or small colored chips. Industrial color matchers view larger fields, such as two 5 × 12-inch panels. The 10 Degree Standard Observer should be used when viewing larger fields. Observers for those experiments viewed a 10° visual field, which is about the size of a fist held at arm’s length.

The standard observers represent combinations of the color matching functions of a number of observers. Standard observer color matching experiments are tedious and difficult to do. Few people can do them with reproducibility. An individual’s color matching functions are likely to vary from that of a CIE Standard Observer. Although these differences do not generally present a problem, they can affect the evaluation of metameric samples.

### 58.4 Calculating Tristimulus Values

Tristimulus values for a reflecting sample are calculated from the following equations:

\[
X = k \int_{380}^{780} R_\lambda S_\lambda x_\lambda d\lambda \equiv k \sum_{380}^{780} R_\lambda S_\lambda x_\lambda \Delta \lambda
\]  
(58.1)

\[
Y = k \int_{380}^{780} R_\lambda S_\lambda y_\lambda d\lambda \equiv k \sum_{380}^{780} R_\lambda S_\lambda y_\lambda \Delta \lambda
\]  
(58.2)

![FIGURE 58.6](image-url) The color matching functions for the CIE 10 Degree Standard Observer.
in which $S_\lambda$ is the relative spectral power distribution of the illuminant at wavelength $\lambda$, $R_\lambda$ is the reflectance factor of the sample at wavelength $\lambda$, and $x_\lambda$, $y_\lambda$, and $z_\lambda$ are the color matching functions of the observer at wavelength $\lambda$. For transmitting objects, substitute the transmission factor, $T_\lambda$, of the sample at wavelength $\lambda$ for the reflectance factor. The factor $k$ normalizes $Y$ so that it will equal 100.00 for a perfect reflector or transmitter, i.e., $R_\lambda$ or $T_\lambda$ is 100.00 at all wavelengths of interest. The summations in the above equations are only valid if the reflectance or transmittance of the sample is measured at wavelength intervals of 1 nm or 5 nm from 380 to 780 nm.

Many commercial spectrophotometers measure wavelength intervals of 10 or 20 nm. To accurately calculate tristimulus values of samples measured with those instruments, the following equations should be used:

$$X = \sum W_{x\lambda} R_\lambda$$

$$Y = \sum W_{y\lambda} R_\lambda$$

$$Z = \sum W_{z\lambda} R_\lambda$$

in which $W_{x\lambda}$, $W_{y\lambda}$, and $W_{z\lambda}$ are weighting factors designed for 10 and 20 nm wavelength intervals. $T_\lambda$ can be substituted for $R_\lambda$ for transmitting samples. Although a number of weighting factors have been developed over the years [2–7], those recommended by ASTM in E 308 Standard Practice for Computing the Colors of Objects by Using the CIE System [7] are recommended.

Tristimulus values for a light source can be calculated easily from measurements taken at 1 or 5 nm intervals from the following equations:

$$X = \frac{k_m \sum S_\lambda \tilde{x}_\lambda}{\sum \tilde{x}_\lambda}$$

$$Y = \frac{k_m \sum S_\lambda \tilde{y}_\lambda}{\sum \tilde{y}_\lambda}$$

$$Z = \frac{k_m \sum S_\lambda \tilde{z}_\lambda}{\sum \tilde{z}_\lambda}$$

in which $S_\lambda$ is the relative spectral power of the light source at wavelength $\lambda$, $k_m$ is the maximum spectral luminous efficacy function (683 lm W$^{-1}$), and $\tilde{x}_\lambda$, $\tilde{y}_\lambda$, and $\tilde{z}_\lambda$ are the color matching functions for the standard observer.

### 58.5 Reflectance Measurements

**Specular and Diffuse Reflectance**

Specular (sometimes called regular) reflection is the mirror-like reflection from an object. If you shine a beam of light on a mirror, it will be entirely reflected at the same angle on the opposite side of a normal
plane to the mirror’s surface. However, if you shine a beam of light on a pellet of compressed barium sulfate (BaSO₄) powder, it will enter the surface, be scattered a number of times, and exit the pellet in many directions. This is called diffuse reflection. Glossy and semiglossy materials contain a combination of specular and diffuse reflection as shown in Fig. 58.7. Observers usually discount the specular reflection when visually evaluating the color of a material.

**Illuminating and Viewing Geometries for Reflectance**

Instruments designed for measuring the color of reflecting objects consist of an illuminator, a sample holder, and a receiver. The CIE has recommended four illuminating and viewing geometries for making reflectance measurements.

Bidirectional geometries illuminate the sample with a narrow beam of light and view the sample with a receiver having a narrow entrance field. In the most commonly used bidirectional geometry, the sample is illuminated at a 45° angle (±2°) from the sample’s normal and viewed along the sample’s normal (±10°). The other recommended geometry illuminates the sample along its normal and views the sample at 45° from its normal. Bidirectional geometries measure only diffuse reflection and can be sensitive to the surface texture of the sample. The two bidirectional geometries produce equivalent results [8, 9].

In the most common diffuse geometry, the illuminator includes an integrating sphere. An integrating sphere is a hollow metal sphere coated with a highly reflecting white coating with openings for the light source, the sample, and the receiver. The instrument’s light source projects a beam of light onto the integrating sphere’s wall. The light is reflected many times by the sphere’s wall, and the sample is illuminated from all angles. When measuring in the diffuse/normal mode, d/0, the receiver views the sample along its normal. When the receiver is positioned in this manner, the specular reflection is directed back towards the light source and is not measured.

For some applications, it is useful to remove the specular reflection off of the sample’s surface from the reflection of the light that is reflected back from the interior of the sample. This can be done by moving the receiver 6 or 8° from the sample’s normal as shown in Fig. 58.8. A specular inclusion port is placed at the equal angle on the opposite side of the sample’s normal. By placing a white plug having the same reflectance as the sphere wall in the port, the specular reflection can be included in the measurement. By using a light trap at the specular inclusion port, some or all of the specular reflection can be excluded from the measurement. The narrower the specular reflection peak, i.e., the glossier the material, the more specular reflection is excluded. Specular included measurements are normally abbreviated SCI, while specular excluded measurements are abbreviated SCE. This geometry is referred to as diffuse/near-normal but still abbreviated d/0. When the specular reflection is included, this geometry is sometimes referred to as total/normal, t/0.

**FIGURE 58.7** A semiglossy material showing a combination of specular and diffuse reflection.
The last of the CIE recommended illuminating and viewing geometries is the normal/diffuse or near-normal/diffuse, 0/d and 0/t. This is the reverse of the d/0 geometry. The illuminator illuminates the sample along its normal, or slightly off of its normal. For this geometry, the integrating sphere is part of the receiver. Light reflected from the sample is captured by the integrating sphere and the remaining optics of the receiver views the sphere wall. The two diffuse geometries produce equivalent results [8, 9].

**Monochromatic and Polychromatic Illumination**

An instrument’s illuminator may illuminate the sample with either a narrow band of wavelengths, 1 to 10 nm wide, called monochromatic illumination, or a wide band of wavelengths, usually simulating a daylight illuminant and called polychromatic illumination. For nonfluorescent samples, either illumination method can be used with equivalent results. However, for fluorescent samples, only polychromatic illumination can produce valid results.

**Sample Texture and Bidirectional Geometries**

Bidirectional illuminating and viewing geometries can be very sensitive to surface texture and any polarization of reflected light. Keeping the illuminator and receiver in the same plane maximizes this sensitivity. To reduce or eliminate this sensitivity, circumferential or annular illumination (or receiving) can be used. When an illuminator provides light (or the receiver possesses responsivity) at many points distributed uniformly around a 45° cone centered at the sample’s normal, we refer to circumferential illumination (or viewing). When the illuminator provides light continuously and uniformly around the cone, we refer to annular illumination (or viewing).

**Which Illuminating and Viewing Geometry Is Best?**

“Which illuminating and viewing geometry is best for color measurement?” is a difficult question to answer [9–12]. For matte samples, all of the geometries produce equivalent results. For high-gloss samples, the diffuse geometries with the specular reflection excluded provide measurements very close to the bidirectional geometries. For semigloss samples, the problem becomes more complex. The two bidirectional geometries are similar to the way a person evaluates color visually and are often thought
to agree better with visual evaluation. On the other hand, the diffuse geometries measured with the specular reflection included minimize the effect of the sample’s texture and gloss and are quite useful for computerized color matching. Rather than purchasing multiple instruments, most users select the geometry most suited to their major needs and compromise on other measurements.

Spectrophotometers

Spectrophotometers are used to measure an object’s reflection characteristics throughout the visible spectrum. Double-beam spectrophotometers monitor a reference standard to compensate dynamically for fluctuations in source output, detector response, and atmospheric absorption to increase the instrument’s stability [13]. Improvements in electronics and optics have allowed single-beam spectrophotometers to achieve the stability of double-beam instruments [14]. Single-beam instruments with an integrating sphere require a correction for the reduction of sphere efficiency caused by sample absorption [14].

Reflectance measurements are referred to as if they take place at a single wavelength. In actuality, a spectrophotometer has a finite spectral bandwidth or bandpass centered about that wavelength. Some instruments will have a bandpass as narrow as 1 nm, while others may exceed 20 nm. Bandpass is important because it influences the color measurement. The extent of this influence depends on the sample being measured [15, 16]. The spectral bandpass should be equal to the wavelength increment used in the calculation of tristimulus values to obtain the best color measurement results [17].

Spectrophotometers must be standardized before making reflectance factor measurements. The high point of the measurement scale is set by measuring a white standard of known reflectance factor [18]. The zero point is set by measuring a light trap or a black calibration standard. Single-beam, integrating sphere spectrophotometers may also require a sphere wall calibration, which is often done with a gray standard.

Some spectrophotometers allow the user to vary the size of the area measured. For most applications, the largest area possible should be measured. A number of documentary standards exist for making and reporting reflectance measurements [9, 17, 19-25].

Colorimeters and Spectrocolorimeters

Colorimeters were developed in the 1920s to 1930s as a less expensive alternative to spectrophotometers for quality control and color difference applications. They are simple to use and directly measure a sample’s tristimulus values or related color coordinates. Three or four filters modify the light source and attempt to duplicate a Standard Illuminant/Standard Observer combination. Because of the difficulty in matching the CIE Illuminant and Standard Observer functions, they are less accurate than spectrophotometers for determining a sample’s tristimulus values. Colorimeters determine the color difference between two samples more accurately than they determine tristimulus values, and they are often called color-difference meters. Since only one Standard Illuminant/Standard Observer combination is usually possible, colorimeters cannot be used to determine metamerism. Standards also exist for making colorimeter measurements [24–26].

A new class of instruments, spectrocolorimeters, began to appear in the 1980s. Spectrocolorimeters are spectrophotometers that only output tristimulus values or related color coordinates. They are less expensive and often have fewer options (such as variable area of view) than fully functional spectrophotometers. However, because they are spectrophotometers, they are capable of measuring metamerism.

Sample Preparation

Accurate color measurement is often dependent on sample preparation. Ideally, a sample for reflectance measurement is flat, has a uniform gloss and texture, is opaque, and is nondirectional. Always strive for sample preparation techniques that are reproducible. Consult standard test methods [24], standard practices [19, 27–29], books and articles [30–33] for help and advice on sample preparation.
58.6 Transmittance Measurement

Regular and Diffuse Transmittance

When a beam of light passes through a “transparent” material along its normal, the intensity of the beam will be decreased by absorption, but the direction of the beam will be unchanged. This is called regular transmittance. When a beam of light passes through a hazy or translucent material along its normal, the material scatters light and spreads the beam. This is called diffuse transmittance.

Illuminating and Viewing Geometries for Transmittance

The CIE has recommended three illuminating and viewing geometries for transmittance measurements. [1] Most transmittance measurements are made with spectrophotometers designed for analytical chemistry applications that use a normal/normal, 0/0, geometry. The illuminator directs the incident beam along the sample's normal, and the receiver views the sample along its normal. Only regular transmittance can be measured accurately using this geometry.

Regular and diffuse transmittance can be measured using the normal/diffuse, 0/d, geometries (or the equivalent diffuse/normal, d/0), which the CIE also recommended for reflectance measurements. Regular transmittance is measured by keeping the sample as far away as possible from the integrating sphere, whereas diffuse transmittance is measured by placing the sample in contact with the sphere. Instruments designed specifically for transmittance measurements would have only a sample or illuminator port and a receiver port. Instruments designed for reflectance measurements can be used for making transmittance measurements by placing a white material in the sample port and using the specular included mode of measurement. The illuminator or receiver port would then serve as the sample port.

The third geometry recommended by the CIE, diffuse/diffuse, d/d, is not often used for industrial color measurement. One integrating sphere is used to illuminate the sample, and a second integrating sphere is used to view the sample.

The two bidirectional reflectance geometries (45/0 and 0/45) have also been used for making regular transmittance measurements.

Monochromatic and Polychromatic Illumination

Instruments for measuring transmittance may have either monochromatic or polychromatic illumination. The transmittance of nonfluorescent samples can be measured using either type of illumination, but fluorescent samples can only be measured using polychromatic illumination.

Standardizing Instruments for Transmittance Measurements

Three techniques exist for setting the high end of the measurement scale, a transmittance factor of 1.0. Each technique produces different results, so it is important to document the method used.

Setting the instrument to read a transmittance factor of 1.0 with no sample in the sample compartment is the easiest technique. The transmittance measurements will then be relative to air. This technique is often used when solid samples are being measured.

Transmittance measurements of solid materials may also be made relative to a clear blank of similar material. To make these measurements, the clear blank is placed in the sample compartment before the instrument is standardized.

When liquids are to be measured, a holder containing solvent or nonabsorbing liquid of the same refractive index as the liquid to be measured should be placed in the sample compartment before standardizing the instrument. This eliminates any effects of the holder's transmittance.

Sample Preparation

Ideal samples will be flat with parallel sides. Liquid sample holders should be made from optical glass. Because transmittance will change with sample thickness and the concentration of colorant, it is impor-
tant that sample holders and blanks used for standardization have the same path length or thickness as the sample. When two different samples must be compared, they should be prepared using the same technique and have the same thickness.

It is extremely difficult to measure the transmittance of curved materials because the curvature of the object may act as a lens and deflect the incident light away from the receiver. If the curvature is not too great, it may be possible to make a diffuse transmittance measurement.

58.7 Color Difference Calculations

A number of equations have been developed over the years for calculating the color difference between two objects [1, 10, 24, 30, 34, 35, 36]. One of the most common equations is the CIELAB recommended by the CIE in 1976 [1].

First the CIELAB coordinates, \( L^* \) (lightness), \( a^* \), \( b^* \), \( C^*_{ab} \) (chroma) and \( h_{ab} \) (hue angle) are calculated with Equations 58.11 through 58.15.

\[
L^* = 116 f(Y/Y_n) - 16 \quad (58.11)
\]

\[
a^* = 500 [f(X/X_n) - f(Y/Y_n)] \quad (58.12)
\]

\[
b^* = 200 [f(Y/Y_n) - f(Z/Z_n)] \quad (58.13)
\]

\[
C^*_{ab} = \sqrt{a^{*2} + b^{*2}} \quad (58.14)
\]

\[
h_{ab} = \arctan[b^*/a^*] \quad (58.15)
\]

in which \( X, Y, \) and \( Z \) are tristimulus values and the subscript \( n \) refers to the tristimulus values of the perfect diffuser for the given illuminant and standard observer; \( f(X/X_n) = (X/X_n)^{1/3} \) for values of \( (X/X_n) \) greater than 0.008856 and \( f(X/X_n) = 7.787(X/X_n) + 16/116 \) for values of \( (X/X_n) \) equal to or less than 0.008856; and the same with \( Y \) and \( Z \) replacing \( X \) in turn. The hue angle is 0° along the \(+a^*\) axis, 90° along the \(+b^*\) axis, 180° along the \(-a^*\) axis, and 270° along the \(-b^*\) axis.

The total color difference, \( \Delta E^*_{ab} \) and its components—the lightness difference, \( \Delta L^* \), the chroma difference, \( \Delta C^*_{ab} \), and the hue difference, \( \Delta H^*_{ab} \)—are calculated using Equations 58.16 through 58.21.

\[
\Delta L^* = L^*_{\text{trial}} - L^*_{\text{standard}} \quad (58.16)
\]

\[
\Delta a^* = a^*_{\text{trial}} - a^*_{\text{standard}} \quad (58.17)
\]

\[
\Delta b^* = b^*_{\text{trial}} - b^*_{\text{standard}} \quad (58.18)
\]

\[
\Delta E^*_{ab} = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2} \quad (58.19)
\]

\[
\Delta C^*_{ab} = C^*_{ab\,\text{trial}} - C^*_{ab\,\text{standard}} \quad (58.20)
\]

\[
\Delta H^*_{ab} = [(\Delta E^*_{ab})^2 - (\Delta L^*)^2 - (\Delta C^*_{ab})^2]^{1/2} \quad (58.21)
\]

A negative value of \( \Delta L^* \) means the trial is darker than the standard, and a negative value of \( \Delta C^*_{ab} \) means the trial has a lower chroma than the standard. When the hue angle, \( h_{ab} \) of the trial is greater than that of the standard, the sign of \( \Delta H^*_{ab} \) is positive, and vice-versa. The total color difference and its components can then be used in setting color tolerances [19, 37].

Researchers have been making modifications to the CIELAB color difference equation in an attempt to have the color difference more closely correlate with visually observed color differences. The CMC(\( l:c \)) color difference equation [50–52] has gained great acceptance in the textile industry and is being tested.
in other areas. Starting with the CIELAB color differences, the CMC(l:c) color differences are calculated with Equations 58.22 through 58.28.

\[
\Delta E = \left[ \frac{\Delta L^*}{s_L} + \left( \frac{\Delta C_{ab}^*}{c_sC} \right)^2 + \left( \frac{\Delta H_{ab}^*}{s_H} \right)^2 \right]^{1/2}
\]

(58.22)

\[
S_L = \frac{0.040975L^*}{1 + 0.01765L^*}
\]

(58.23)

unless \(L^* < 16\), in which case \(S_L = 0.511\),

\[
S_C = \frac{0.0638C_{ab}^*}{1 + 0.0131C_{ab}^*} + 0.638
\]

(58.24)

\[
S_H = (FT + 1 - F)S_C
\]

(58.25)

\[
F = \left( \frac{C_{ab}^+}{C_{ab}^+ + 1900} \right)^{1/2}
\]

(58.26)

\[
T = 0.36 + \text{abs}(0.4 \cos(35 + h_{ab}))
\]

(58.27)

unless \(h\) is between 164° and 345° when

\[
T = 0.56 + \text{abs}(0.2 \cos(168 + h_{ab}))
\]

(58.28)

in which the notation “abs” indicates the absolute (i.e., positive,) value of the term inside the square brackets. When \(l = c = 1\), the formula quantifies the perceptibility of color differences. Optimum values of \(l\) and \(c\) for quantifying the acceptability of a color match must be determined for the material being measured. The textile industry has found the optimum values to be \(l = 2\) and \(c = 1\) [51].

In 1994, the CIE recommended a new color difference equation, CIE94 [36], which is similar to the CMC equation. CIE94 color differences are calculated using Equations 58.29 through 58.33. The perceived color-difference, \(\Delta V\), is related to the measured color difference through an overall sensitivity factor, \(k_e\).

\[
\Delta V = \frac{1}{k_e} \Delta E_{94}^*
\]

(58.29)

\[
\Delta E_{94}^* = \left[ \frac{(\Delta L^*)^2}{k_Ls_L} + \left( \frac{\Delta C_{ab}^*}{k_cC_sC} \right)^2 + \left( \frac{\Delta H_{ab}^*}{k_Hs_H} \right)^2 \right]^{1/2}
\]

(58.30)

\[
S_L = 1
\]

(58.31)

\[
S_C = 1 + 0.045C_{ab}^*
\]

(58.32)

\[
S_H = 1 + 0.015C_{ab}^*
\]

(58.33)
The overall sensitivity factor, $k_E$, is used to account for variation in the illuminating and viewing conditions. A person in the textile industry who is using CMC(2:1) and would like to compare the results with CIE94 would set $k_L = 2$ and $k_C = k_H = 1$, i.e., CIE94(2:1:1).

The improvement in correlating with visual assessments of color difference could result in either the CMC($k_C$) or the CIE94 replacing the CIELAB color difference equation. Hunter and Harold [30] detail many of the older color difference equations, many of which are still in use. A history of the development of color metrics was written by Richter [53].

58.8 Special Cases

Fluorescent Samples

Fluorescent materials not only reflect light but also emit light. Light absorbed at some wavelengths is emitted at longer wavelengths. The amount of light emitted depends on the intensity and the spectral power distribution of the source. Because of the emission of light, spectrophotometers that illuminate a fluorescent material with monochromatic light cannot be used, because the light emitted at the longer wavelengths will be measured as if it had been reflected from the material. Reflectance measurements of the material illuminated by polychromatic light will include the emitted light at the proper wavelengths. If the instrument's light source is a good representation of the illuminant, the measurement will be indicative of the observed color. Techniques have been recommended by the CIE for assessing the quality of daylight simulators [55]. Measured reflectance factors at the wavelengths of emittance may be greater than 1.0. Special fluorescent calibration standards must be used to accurately measure these materials [38]. The 45/0 or 0/45 bidirectional geometries are recommended for measuring fluorescent materials [39, 40].

The complete analysis of a fluorescent material requires that the emittance be separated from the reflectance. Spectrofluorimeters were designed to analyze fluorescent samples. These instruments illuminate the sample with monochromatic light. Reflected and emitted rays pass through a second monochromator to isolate the receiver wavelengths. By viewing the sample at the same wavelength as it is illuminated, the true reflectance of the sample can be determined. Either the excitation spectra or the emittance spectra can be studied by setting each monochromator at different wavelengths. Techniques have also been developed to correct spectrophotometric measurements of fluorescent samples [54, 56].

Metallic and Pearlescent Samples

Materials that contain metallic and/or pearlescent pigments are goniochromatic, i.e., they change color with the illuminating and viewing geometry. Goniospectrophotometers are needed to measure these materials. A goniospectrophotometer illuminates (or views) the sample at a fixed angle, usually 45°, and views (or illuminates) the sample at three or more angles. The position of the receivers (or illuminators) is described by the aspecular angle, the viewing angle measured from the direction of the specular reflectance, which is equal and opposite the angle of illumination. In a goniospectrophotometer that illuminates the sample at 45° and views at three angles, one of the viewing angles would be near the specular reflection at about 25°, the second at the CIE recommended bidirectional angle of 0° and the third would be far away from the specular reflectance at about 70°.

Goniospectrophotometry is still in its infancy and the CIE recommendations and ASTM standards for making these measurements are still under development.

Retroreflecting Samples

Highway signs and high visibility clothing are examples of retroreflectors. Light shining on a retroreflector is returned in directions very close to the illumination angle. Most retroreflectance measurements are made in connection with highway safety. There are only a few specially built instruments for measuring retroreflection. A projector is usually used to illuminate the sample, and a teleradiometer or a radiometric
telecolorimeter is used to view the sample. Tristimulus values can be calculated from the retroreflectance factors. Standard practices and test methods exist for specifying the illuminating and viewing geometries and making retroreflectance measurements [41–45].

**Lamps, Light Sources, and Displays**

Spectral radiometers and radiometric colorimeters were designed to measure lamps, light sources, and displays. These instruments are similar to spectrophotometers and colorimeters but do not need an illuminator, because the sample being measured emits light.

Lamps and light sources can either be measured directly or by measuring the reflectance of a stable white reflecting surface being illuminated by the lamp or light source. To measure televisions, computer monitors, and other similar devices, the emitted light must usually be imaged directly on the optics of the spectral radiometer or radiometric colorimeter [46, 47].

**Hazy and Translucent Materials**

Hazy and translucent materials are measured by placing them in contact with an integrating sphere and measuring their diffuse transmittance. A haze index can be calculated from four diffuse transmittance measurements on a reflecting spectrophotometer [48]. Two of the measurements are made with a white material in the reflectance sample port, and two measurements are made with a light trap in the port. Special instruments called hazemeters were designed to make haze measurements.

### 58.9 Instrument Manufacturers

Costs of color measuring instruments vary significantly. The more accurate instruments with the best repeatability and reproducibility can be expected to cost more. Table 58.1 lists the price ranges for various types of color measuring instruments. There is a classification in the table called spectral analyzers. Although these instruments may provide information that makes them appear to be colorimeters or spectrophotometers, they use measurement techniques not traditionally associated with those instruments. For example, several use LEDs instead of more traditional light sources. Since the instruments vary so widely in capability, the purchaser must ensure that a particular instrument has the capability to make the measurements desired with sufficient accuracy, repeatability, and reproducibility.

Table 58.2 provides contact information for a number of manufacturers of color measuring instruments. The manufacturers listed in this table design instruments specifically for color measurement. Thus, manufacturers of analytical spectrophotometers are excluded even if their instruments have color measuring capabilities. The table is also limited to manufacturers with a major presence in the U.S.
58.10 Defining Terms

For a more extensive collection of terms relating to color and appearance, the reader should refer to ASTM E 284 Standard Terminology of Appearance [49].

Chroma: Attribute of color used to indicate the degree of departure of the color from a gray of the same lightness.

CIE standard observers: The ideal colorimetric observer data adopted by the CIE to represent the response of the average human eye, when light-adapted, to an equal-energy spectrum. The standard observer adopted in 1931 was developed from data obtained with a 2° field of vision and is commonly called the “2° standard observer.” The standard observer adopted in 1964 was developed from data obtained with a 10° annular field of vision and is commonly called the “10° standard observer.”
CIE tristimulus values: Amounts of the three mathematical lights necessary in a three-color additive mixture required for matching a color in the CIE System. They are designated \(X\), \(Y\), and \(Z\). The illuminant and standard observer color matching functions must be designated.

colorimetry: The science of color measurement.

hue: The attribute of color perception by means of which a color is judged to be red, orange, yellow, green, blue, purple, or intermediate between adjacent pairs of these, considered in a close ring (red and purple being an adjacent pair.) White, black and grays possess no hue.

illuminant: A mathematical description of the relative power emitted by a real or imaginary light source at each wavelength in its emission spectrum.

lightness: (1) The attribute of color perception by which a nonself-luminous body is judged to reflect more or less light. (2) The attribute by which a perceived color is judged to be equivalent to one of a series of grays ranging from black to white.

metamerism: Property of two specimens that match under a specified illuminator and to a specified observer and whose spectral reflectances or transmittances differ in the visible wavelengths.

perfect reflecting diffuser: Ideal reflecting surface that neither absorbs nor transmits light, but reflects diffusely, with the radiance of the reflecting surface being the same for all reflecting angles, regardless of the angular distribution of the incident light.

reflectance: Ratio of the reflected radiant or luminous flux to the incident flux in the given conditions. The term reflectance is often used in a general sense or as an abbreviation for reflectance factor. Such usage may be assumed unless the above definition is specifically required by the context.

reflectance factor: Ratio of the flux reflected from the specimen to the flux reflected from the perfect reflecting diffuser under the same geometric and spectral conditions of measurement.

Optical Loss

59.1 Basic Concepts

Different properties of optics are used in many instrumentation and measurement devices. Applications vary from photographic imaging to high-speed data transmission via fibers. Once the light is generated and propagated from a source, it can be expanded, condensed, collimated, reflected, polarized, filtered, diffused, absorbed, refracted, scattered, etc. for manipulation and processing. Some of these manipulations are done to serve a particular purpose, and some results from physical characteristics of the light and optical properties of the media. In many applications, the intensity of light at the beginning will not be the same at the end due propagation characteristics and losses. It is important to point out that the word “light” is usually taken as radiation in the range of from about 380 nm to about 800 nm. This understanding limits important applications to those in the near-infrared and ultraviolet regions of the spectrum. In here, when the term “light” is used, the IR and UV portions of the spectrum are not left out.

The interpretation and treatment of “optical loss” is different for each individual instrumentation and measurement activity. It entirely depends on the purpose and method of measurements. For example, scattering of the light (radiation) from clouds is a useful property for determining atmospheric characteristics, whereas scattering of light in optical fibers may not be desirable due to resulting losses in power and decrease in efficiency. While many instrumentation systems (e.g., imaging) make use of scattering, absorption, refraction, and reflection as useful properties, in others these are considered to be mere losses that cause undesirable attenuations. In recent years, fiber optics has attracted considerable attention, and most of the following discussion on optical loss is centered on this subject. Likewise, this chapter concentrates on optical losses in fiber optics to clearly demonstrate the fundamental principles. Nevertheless, it is important to recognize that the same as losses in fiber optics may not be regarded as losses in other applications. It will be shown here that losses in fiber optics have useful properties in determining the optical fiber characteristics.

Theoretically, light propagation in fibers can be treated in a number of ways. For example, in treating propagation by modes, the fibers are viewed as optical waveguides, whereas treatment by rays is an approximate description of fibers with diameters much greater than the wavelength. In this chapter, both approaches will be used as appropriate.
An optical fiber is a circular dielectric glass (some polymers are also used) waveguide that can efficiently transport optical energy, and the information in the energy, usually by using the principle of total internal reflection. In some cases, it consists of a central glass core surrounded by a concentric cladding material with a slightly lower (\(\leq 1\%\)) refractive index. Since the core has higher index of refraction than the cladding, light is confined to the core if the angular condition of total internal reflection is met. Attenuation of the light begins the moment light enters the fiber. The acceptance and transmission of light depends greatly on the angle at which the light enters the fiber. The angle must be less than the critical acceptance angle of the particular fiber being used, as shown in Figure 59.1.

There are three basic types of fibers: single-mode step-index, multimode graded index, and multimode step index, as shown in Figures 2a, 2b, and 2c, respectively. The characteristics of optical losses in these three types of fibers vary slightly due to differences in construction and the nature of propagation of light. For example, in the case of multimode step-index fibers, light striking the core–cladding junction at an angle greater than the angle of internal reflection passes through and becomes absorbed by the opaque jacket. This represents a significant source of attenuation, limiting the injection efficiency at the transmitting end.

Single-mode fibers, Figure 59.2a, are used in transmitting broadband signals over large distances. Their attenuation is generally very small, and their transmission band is large. Owing to material properties, low attenuations can be expected for wavelengths around 1.3 to 1.6 µm. Additional attenuation arises from splices and fiber bending.

Multimode graded-index fibers have medium size cores (50 to 100 µm) and refractive indices that decrease radially outward. The two optical materials with different refractive indices are mixed together in such a way that the index of refraction decreases smoothly with distance from the fiber axis. The graded index causes the light to gradually bend back and forth across the axis in sinusoidal manner when very small injection angles are used. This greatly reduces the light losses from the fiber and results in relatively better bandwidth and efficiency. The graded-index fibers also allow the use of simpler splicing techniques.

Good-quality fibers are typically made of pure silica with index modifying dopants such as GeO₂. While bandwidth is the primary consideration in the use of fiber optics in communication applications, light attenuation characteristics are equally important. The overall quality of a fiber optic light guide is determined by its light transmissivity, defined as the ratio of the output light to that put into the fiber.

![Diagram of light entering an optical fiber](image)

**FIGURE 59.1** An optical fiber is a circular dielectric glass waveguide that can efficiently transport optical energy. It consist of a central glass core surrounded by a concentric cladding material. An important requirement for the connection of a light source is that a sufficient amount of useful light must be coupled into the fiber. The core has a higher index of refraction than the cladding; therefore, light is confined to the core only if the angular condition of total internal reflection is met. The acceptance and transmission of light depend greatly on the angle at which the light rays enter the fiber, and it must be less than the critical acceptance angle of a particular fiber.
LEDs are the primary light source used in fiber-optic links for bit rates up to 200 Mb/s and distances up to 2 km. For higher bit rates and longer distances, diode lasers are preferred. LEDs used in fiber-optic applications operate at three narrowly defined wavelength bands 650, 820 to 870, and 1300 nm. The choice of wavelength is also determined by the transmission characteristics of optical fibers.

59.2 Optical Loss Mechanisms in Optical Fibers

There are two basic categories of sources of light loss in the fiber optic systems: extrinsic and intrinsic losses.
Extrinsic Fiber Losses

These losses are specific to geometry and handling of the fibers and are not functions of the fiber material itself. There are three basic types:

- bending losses
- launching losses
- connector losses

Bending Losses

Bending losses are the result of distortion of the fiber from the ideal straight-line configuration. While the light is traveling inside the fiber, part of the wavefront on the outside of the bend must travel faster than the part of the smaller inner radius of the bend. Since this is not possible, a portion of the wave must be radiated away. Losses are greater for bends with smaller radii, particularly for kinks or microbends in a fiber.

An important cause of attenuation is due to microbending of the fiber. Microbending is due to irregularly distributed undulations in the fiber with radii of curvature of a few millimeters and deviations from the mean line of a few micrometers, as exemplified in Figure 59.3. Microbends arise from mechanical tensile forces by which the fiber is pressed against a rough surface. Although the effect of variations in diameter can be discussed at length by waveguide theory, here it will be sufficient to say that those components of the light that are traveling in the fiber near its acceptance limit cross outside this boundary and are lost from the fiber. These losses may be avoided by careful cable constructions, avoiding excessive mechanical forces, and controlling the temperature variations of the cable. This is achieved by a loose encasing of the fiber in a plastic sheath or by covering the fiber with soft flexible material, as shown in Figure 59.4.

Launching Losses

The term launching loss refers to an optical fiber not being able to propagate all the incoming light rays from an optical source. These occur during the process of coupling light into the fiber (e.g., losses at the interface stages). Rays launched outside the angle of acceptance excite only dissipative radiation modes in the fiber. In general, elaborate techniques have been developed to realize efficient coupling between the light source and the fiber, mainly achieved by means of condensers and focusing lenses. The focused input beam of light needs to be carefully matched by fiber parameters for good coupling.
Equally, once the light is transmitted through the fiber, output fiber characteristics must also match the output target characteristics to be able to couple the largest proportion of the transmitted light. This can be done by a suitable focusing lens arrangement in the output end.

There are also initial face (Fresnel) losses due to reflections at the entrance aperture. The Fresnel losses are greater if the fiber/source is air coupled. Hence, most optical couplings to a fiber utilize index matching materials, thus reducing coupling loss substantially.

**Connector Losses**

Connector losses are associated with the coupling of the output of one fiber with the input of another fiber, or couplings with detectors or other components. The significant losses may arise in fiber connectors and splices of the cores of the joined fibers having unequal diameters or misaligned centers, or if their axes are tilted. Mismatching of fiber diameters causes losses that can be approximated by $-10 \log(d/D)$.

There are other connection losses such as offsets or tilts or air gaps between fibers, and poor surface finishes. Some of these are illustrated in Figure 59.5.

To take full advantage of fiber characteristics in transmission systems of very low intrinsic attenuation, the contribution of losses from other sources must also remain very small. The attenuation $a_c(d)$ due to coupling efficiency may be expressed as:

$$a_c(d) = -10 \text{ dB log}\eta(d)$$  \hspace{1cm} (59.1)

where $\eta(d)$ is the coupling coefficient.

In general, the positions and shapes of the fiber cores are controlled to tight manufacturing tolerances. Fibers having attenuations greater that 1 dB/km are rarely used in communication networks. Nevertheless, the attenuation of badly matched fibers may exceed 1 dB/km per connector or splice if they are badly handled during installation stages. A good coupling efficiency requires precise positioning of the fibers to center the cores. The simplest way to avoid connector losses is by splicing the two ends of the fibers permanently, either by gluing of by fusing at high temperatures.

Losses in gaps can be viewed as a type of Fresnel loss because existing air space introduces two media interfaces and their associated Fresnel reflection losses. In this case, there are two major losses to be considered. The first loss takes place in the inner surface of the transmitting fiber, and the second loss occurs due to reflections from the surface of the second fiber. One way of eliminating these losses is by introducing a coupler that matches the optical impedances of the two materials. This arrangement results in matched reflection coefficients, which is analogous to matching of impedances.
Intrinsic Fiber Losses

Intrinsic fiber losses are those associated with the fiber optic material itself, and the total loss is proportional to length $L$. Once inside the fiber, light is attenuated primarily because of absorption and scattering; therefore, these are the primary causes of the losses.

Absorption Losses

As in the case of most transmissive systems, light loss through absorption in an optical fiber tends to be an exponential function of length. Absorption loss is caused by the presence of impurities such as traces of metal ions (e.g., Cu$^{2+}$, Fe$^{3+}$) and hydroxyl (OH$^-$) ions. Optical power is absorbed in the excitation of molecular vibrations of such impurities in the glass, as illustrated in Figure 59.3. One characteristic of absorption is that it occurs only in the vicinity of definite wavelengths corresponding to the natural oscillation frequencies or their harmonics of the particular material. In modern fibers, absorption losses are almost entirely due to OH$^{-1}$ ions. The fundamental vibration mode of these ions corresponds to $\lambda = 2.73$ $\mu$m and the harmonics at 1.37 and 0.95 $\mu$m. It is possible to employ dehydration techniques during manufacturing to reduce presence of OH$^{-1}$ ions.

Unlike scattering losses, which are relatively wideband effects, absorption losses due to each type of impurity act like a band-suppression filter, showing peak absorption at well defined wavelengths.
Scattering Losses

Despite the careful manufacturing techniques, most fibers are inhomogeneous that have disordered, amorphous structures. Power losses due to scattering are caused by such imperfections in the core material and irregularities between the junction and cladding as shown in Figure 59.3.

Inhomogeneities can be either structural or compositional in nature. In structural inhomogeneities, the basic molecular structure has random components, whereas, in compositional inhomogeneity, the chemical composition of the material varies. The net effect from either inhomogeneity is a fluctuation in the refractive index. As a rule of thumb, if the scale of these fluctuations is on the order of $\lambda/10$ or less, each irregularity acts as a scattering center. This is a form of Rayleigh scattering and is characterized by an effective absorption coefficient that is proportional to $\lambda^{-4}$. Rayleigh scattering can be caused by the existence of tiny dielectric inconsistencies in the glass. Because these perturbations are small with respect to the waves being propagated, light striking a Rayleigh imperfection scatters in all directions. Scattering losses are less at longer wavelengths, where the majority of the transmission losses are due to absorption from impurities such as ions. Rayleigh scattering losses are not localized, and they follow a distribution law throughout the fiber. However, they can be minimized by having low thermodynamic density fluctuations.

A small part of the scattered light may scatter backward, propagating in the opposite direction. This backscattering has important characteristics and may be used for measuring fiber properties. Usually, the inhomogeneities in the glass are smaller than the wavelength $\lambda$ of the light. The scattering losses in glass fibers approximately follow the Raleigh scattering law; that is, they are very high for small wavelengths and decrease with increasing wavelength.

In general, optical losses in the glass cause the optical power in a fiber to fall off exponentially with the length $L$ of the fiber,

$$P(L) = P(0) 10^{\left(-\alpha L/10\text{dB}\right)} \quad (59.2)$$

where $P(0) =$ optical power that couples to the fiber, $P(L) =$ power remaining after length $L$, and $\alpha$ is the attenuation coefficient indicating the rate of loss of optical power in dB/km.

The product $\alpha L$ is called the attenuation of the fiber. An attenuation of 10 dB means that the optical power $P(L)$ at the end of the fiber is only 10% of the initial power $P(0)$. A 3-dB attenuation gives 50%, and 1 dB is about 80%.

A typical attenuation coefficient $\alpha$ against wavelength $\lambda$ is shown in Figure 59.6 for common low-loss fused silica fiber. The optical losses for wavelengths below 1 µm are mainly due to Rayleigh scattering. At larger wavelengths absorption losses are important, notably at 1.4 µm through absorption by OH$^{-1}$ ions. Above 1.6 µm, absorption due to impurities becomes dominant. Because of attenuations, only limited wavelength ranges are appropriate for optical data transmission.

Although intrinsic fiber losses can be associated with the core index $n_c$, the core index has an important role in determining the propagation time delay of optical signals. The propagation time delay $t_p$ may be expressed by

$$t_p = n_c L/c \quad (59.3)$$

where $c =$ velocity of light in the fiber, and $L =$ fiber length.

Another type of loss in optical fibers occurs due to the propagation of light at different angles. Light propagating at shallow angles is called low-order mode, and light propagating at larger angles is called high-order mode. For a given length of fiber, the high-order modes reflect more often and cover longer distances than the low-order modes. Therefore, high-order modes suffer more losses, thus causing modal dispersions. The modal dispersion is one of the primary cause of rise time degradation for increasing fiber wavelengths. In addition, propagation time varies with index of refraction, so different wavelength components of the source spectrum have different travel times, thus causing chromatic dispersion.
Optical time domain reflectometers (OTDRs) are used mainly for link testing. In this instrument, optical power is launched into the fiber, and the reflected power associated with Rayleigh scattering and other backscattering mechanisms are measured in the sending end, as shown in Figure 59.7. Manufacturers usually provide the instrument with customized analysis software and optical modules to be integrated into a computer. OTDR complements attenuation measurements by measuring the backscattering. This permits not only the attenuation of the complete fiber to be measured but also different attenuation coefficients of fiber segments, as well as optical losses in connectors and splices. Furthermore, it indicates the location of such optical losses as well as the length of the fiber.

**FIGURE 59.6** Attenuation characteristics of a typical optical fiber. The attenuation coefficient $\alpha$ varies with wavelength for all low-loss fused silica fibers due to Rayleigh scattering and impurity absorptions. The optical losses for wavelengths below 1 $\mu$m are mainly due to scattering. At greater wavelengths, absorption losses are important, notably at 1.4 $\mu$m through absorption by OH$^-$ ions. Above 1.6 $\mu$m absorption due to impurities becomes dominant.

**FIGURE 59.7** Optical time domain reflectometers (OTDRs) are used in link tests. The optical power is launched into the fiber, and the reflected power associated with Rayleigh scattering is measured from the same sending end. OTDRs usually are offered with customized analysis software and optical modules to be integrated into a computer. OTDR complements attenuation measurements by measuring the backscattering. This permits not only the attenuation of the complete fiber to be measured but also different attenuation coefficients of fiber segments, as well as optical losses in connectors and splices.
In OTDRs, as Figure 59.8 illustrates in block diagram form, short, intense laser pulses with duration $\Delta t = 10$ to 100 ns at peak power $M_a(0)$ are coupled to the fiber. Backscattering echoes are detected from different regions of the fiber. In traversing the fiber, the power of these impulses decreases exponentially with the length of the fiber, predominantly due to scattering. A small portion of the scattered light reverses its direction and returns to the transmitter. The returned signal is uncoupled from the fiber by means of a beam splitter, to be processed further. The time history of the returned signals can be expressed as:

$$P_R(t) = K_R M_a(0) \Delta t 10^{(-20\alpha L/10 \text{ dB})}$$

(59.4)

where $K_R$ = the backscattering factor of the fiber.

The backscattering factor depends on scattering and numerical aperture. It is small, such that $P_R(t)$ is reduced as compared to $M_a(0)$, typically by a factor of 50 to 60 dB. Despite this reduction, it is possible to measure the characteristics of fibers that are several kilometers long. In many cases, light pulses with high energy contents are used, along with sensitive receivers based on avalanche photodiodes.

The evolution with time of the backscattering signal $P_R(t)$ is given in Figure 59.9. If the attenuation coefficient and backscattering factors were constant throughout the length of the fiber, a curve that decreases exponentially from left to right would result. However, some power is reflected back from the end of the fiber because of some discontinuity. This appears as a sharp pulse at the right-hand side of the curve. In practical fibers, local optical losses as well as continuous losses occur due to imperfect connectors and splices. From the location and height of the steps, the position and magnitude of the local losses can easily be identified. The length of the fiber can also be obtained from timing of this pulse.

Other disturbances in the propagation of the light are also revealed in the backscattering signal. For example, variations in the attenuation coefficient of spliced fiber segments can be seen as slope changes in the $P_R(t)$ curve. In such cases, all information of importance can be drawn from the backscattering signal to enable the calculation of the attenuation and the local attenuation coefficients. A practical advantage of this method is that in measurements only one end of the fiber needs to be accessible; therefore, measurements can be done on optical cables that have already been laid.

**FIGURE 59.8** OTDRs usually come with a laser source, with modules that allow wavelength selection. The short, intense laser pulses with high peak power are coupled to the fiber. Backscattering echoes are detected from different regions of the fiber. The returned signal is uncoupled from the fiber by means of a beam splitter, to be processed further for analysis.
In practical applications of optical fibers, it is necessary to have quantitative knowledge on the whole range of properties. Most important properties are length, attenuation, and bandwidth of the fibers, along with external diameter, core diameter, numerical aperture, and refractive index profile. The actual performance of installed links may be different from the desired performance. Therefore, it is important that both individual components and the entire assembled system undergo testing to verify compliance with the required operations. Additional testing may be conducted over the life of the system to ensure continued functional operation over long periods of time.

There are two basic standard fiber optic attenuation tests: the component acceptance test and the link test. The component acceptance test is performed prior to installation to verify the power and performance acceptance levels of each fiber. The acceptance testing of a functional module begins with power testing of the transmitter. The testing is done by attaching the module set into a reference link and verifying the data rates and bit error rates taken at the other end of the fiber, as shown in Figure 59.10.

Fiber acceptance testing also requires power testing, which can be done by launching a known power from a reference source, as explained in the OTDR section. The functional testing verifies power budget of coupling attenuation effects as well as bandwidth for the fiber. The attenuation and power transmission depend on the mode distribution within the fiber. In short fibers, higher modes dominate, whereas in

**FIGURE 59.9** A typical example of the evolution of a backscattering signal in time. An exponential curve that decreases from left to right is obtained due to attenuation coefficients and backscattering factors. Some power reflects back from the end of the fiber and other discontinuities such as glass-air boundaries, appearing as sharp pulses. From the location and height of these returned sharp pulses, the positions and magnitudes of the local losses can easily be identified. The change of slope of curve also indicates the change in attenuation coefficient if different fibers are used.

**59.4 Standard Field Fiber Optic Attenuation Test**

In practical applications of optical fibers, it is necessary to have quantitative knowledge on the whole range of properties. Most important properties are length, attenuation, and bandwidth of the fibers, along with external diameter, core diameter, numerical aperture, and refractive index profile. The actual performance of installed links may be different from the desired performance. Therefore, it is important that both individual components and the entire assembled system undergo testing to verify compliance with the required operations. Additional testing may be conducted over the life of the system to ensure continued functional operation over long periods of time.

There are two basic standard fiber optic attenuation tests: the component acceptance test and the link test. The component acceptance test is performed prior to installation to verify the power and performance acceptance levels of each fiber. The acceptance testing of a functional module begins with power testing of the transmitter. The testing is done by attaching the module set into a reference link and verifying the data rates and bit error rates taken at the other end of the fiber, as shown in Figure 59.10.

Fiber acceptance testing also requires power testing, which can be done by launching a known power from a reference source, as explained in the OTDR section. The functional testing verifies power budget of coupling attenuation effects as well as bandwidth for the fiber. The attenuation and power transmission depend on the mode distribution within the fiber. In short fibers, higher modes dominate, whereas in

**FIGURE 59.10** The measurements of transmission properties of laid optical fibers are obtained by end-to-end tests. The testing is done by attaching the module set into a reference link and verifying the data rates and bit error rates taken at the other end of the fiber.
long fibers, power is more concentrated in lower order modes. Mode stripping is often used by introducing small bends into the fiber to correlate the performance of tested fiber to actual in-service performance.

In addition to acceptance tests, fibers undergo other tests such as pull strength, breaking, humidity resistance, prolonged tension, and bend tests. Connectors, splitters, combiners, and fiber amplifiers need to be tested frequently to minimize power transmission losses.

In almost all fiber optics, low noise and very sensitive photodetectors are used in measurements. Semiconductor photodiodes made from silicon are suitable for measurements with wavelengths below 1 µm. For larger wavelengths, other detectors are used, such as those made of germanium.

Semiconductor photodiodes work via the internal photoelectric effect; that is, they absorb photons of energy $h\nu$ containing the incoming light beam power $P$ and emit a number of electrons proportional to the number of photons, creating a current:

$$i_p = \frac{n}{h} \frac{P}{e} \eta$$

where $h$ = Planck’s constant, $\nu$ = frequency of the absorbed light ($\nu = c/\lambda$), $\eta$ = a constant of proportionality or quantum efficiency ($\eta < 1$), and $e$ = the charge of an electron.

Photodetectors are used to measure the attenuation in fibers by measuring the optical power in the input $P(0)$ and power $P(L)$ at the end of the fiber. From Equation 59.1, the attenuation of the fiber can be calculated as:

$$a_0 = a_L = -10 \log \frac{P(L)}{P(0)}$$

When photodetectors are used Equation 59.4 can be written as

$$a_0 = -10 \log \frac{i_p(L)}{i_p(0)}$$

It is worth noting that optical power is proportional to current $i_p^2$, not to $i_p$.

Light-emitting diodes (LEDs) or incandescent halogen lamps are suitable for use as light sources for attenuation measurements. If LEDs are used, several interchangeable ones are needed, suitable to different wavelengths to make measurements. On the other hand, halogen lamps yield a wide spectrum of radiation, from which light of various wavelengths can be filtered with a monochromator that uses optical filters, prisms, or diffraction gratings. With an arrangement of this kind, the attenuation of the fiber can be measured as a function of the wavelength of the light.

To measure small optical powers precisely for the purpose of determining attenuation, the photodetector is usually connected to a selective amplifier, and the light source is modulated at low frequency (e.g., 400 Hz) using a rotating disk called a chopper. The selective amplifier amplifies only the similarly modulated components of the photocurrent, so that detector noise and the influence of background light are suppressed. For this purpose, frequency-selective level meters or lock-in amplifiers are often used. In both cases, the frequency and phase of the modulation are fed back in the form of reference voltage.

### 59.5 Out-of-Plane Scattering and Polarization Methods

The art of scatter measurements has long been evolved to established forms within the optics industry. Scatter methods provide extremely sensitive measurements in many diverse applications. There are two basic instruments developed for this purpose; the scatterometer and the polarimeter.

The basic setup for a scatterometer is given in Figure 59.11. Measured scatter is a good indicator of surface quality as well as discrete defects. However, the scattered signals are generally small compared to the specular beams, and they can vary by several orders of magnitude in just a few degrees. Therefore, scatter measurements need sophisticated instrumentation and the signal processing is more complex than many other optical techniques. Usually, for successful applications, the system specifications and measurements must be given in terms of accepted, well defined quantities. Scatter methods are used
routinely as a quality check on optical components in fiber-optic applications. Conversion of surface scatter data to other required formats, such as surface roughness, is common practice. Out-of-plane measurements and polarization-sensitive measurements are areas currently experiencing rapid advancements.

Another instrument in common use is the polarimeter, which senses the polarization of scattered light. The scattering characteristics of a sample are generally described by its bidirectional reflectance distribution function. The reflectance distribution function is the ratio of scattered flux in a particular direction to the flux of an incident beam. The scattered light is often a sensitive indicator of surface conditions. A small amount of surface roughness may reduce the specular power by less than 1% while increasing the scattered power by orders of magnitude. The retardance, attenuation, and depolarization of scattered light similarly provide sensitive indicators of conditions, such as uniformity of refractive index, orientation of surface defects, texture, strain, subsurface damage, coating microstructure, and the degree of multiscattering. Among many other methods, the use of prisms helps polarization and depolarization of the scattered light.

Instrument manufacturers are listed in Table 59.1, along with contact information.

Additional Information

60.1 Basic Concepts of Polarization

Polarization of light is a property of electromagnetic (EM) waves, which include heat, microwaves, radio waves, and x-rays. An EM wave has orthogonal electric and magnetic fields associated with it which vibrate in directions perpendicular to the direction of propagation. The electric field of a sinusoidal EM wave, in particular, can always be decomposed into two orthogonal components; each component has an amplitude and a phase. The amplitude is the maximum value of the field component, and the light intensity is proportional to the square of the amplitude. The phase, referred to a fixed position or time, tells what part of the cycle the electric field is vibrating in. G. G. Stokes pointed out in 1852 that these two orthogonal components do not interfere in amplitude but are additive according to vector algebra \[1\]. When the two orthogonal components are in phase, the EM wave is \textit{linearly polarized}. When the two orthogonal components have the same amplitude and a relative phase of 90°, the EM wave is \textit{circularly polarized}. In general, an EM wave has arbitrary amplitudes and phases for the two orthogonal fields and is elliptically polarized. The concept of polarization ellipse and the descriptions for the polarization of an EM wave in terms of Jones vectors and Stokes vectors are given in the subsection, “Polarization of an EM Wave,” and also in References 1 through 9.

Light is composed of an ensemble of EM waves. A group of EM waves traveling in the same direction can have some linearly polarized waves, some circularly polarized waves, and some elliptically polarized
waves. When they are combined, resulting light can be unpolarized, partially linearly polarized, or partially elliptically polarized. Unpolarized light occurs when there are no fixed directions of the electric field and also no fixed phase relations between the two orthogonal field components. In general, light is partially polarized and can be decomposed into unpolarized light and elliptically polarized light. These concepts are described in terms of Stokes vector in the subsection, “Polarization of Light,” and also in References 1 through 6.

Polarized light can be produced by passing light through a polarizer. An ideal polarizer transmits only light whose electric field is parallel to the transmission axis of the polarizer and rejects light with the orthogonal field. Polarization of light can be observed by stacking two polarizers together and turning one with respect to the other. The transmitted light intensity through these two polarizers will vary, and at some particular positions it will vanish. In this case, light is linearly polarized after passing through the first polarizer. When the second polarizer is turned until its axis is perpendicular to the axis of the first polarizer, light cannot pass through the second polarizer. The transmitted intensity varies according to the square of the cosine of the angle between the two polarizers [5, 9–12]. Real polarizers are not perfect and transmit light with minimum intensity $I_{\text{min}}$ when the polarizer axis is perpendicular to the polarization of purely linearly polarized incident light. This is caused by the small depolarization of a polarizer [12]. Depolarization is a mechanism that turns polarized light into unpolarized light and is the opposite effect of polarization. The maximum transmitted intensity $I_{\text{max}}$ occurs when the polarizer axis is parallel to the incident polarization direction. The extinction ratio of a polarizer is defined as $I_{\text{min}}/I_{\text{max}}$.

Besides the polarizer, another basic element in polarization measurements is the phase retarder or wave plate. A phase retarder changes the relative phase between the two orthogonal fields of an EM wave [4–11]. The change of relative phase between the two orthogonal components is called the phase retardation or retardance. The retardance of a quarter-wave retarder is 90°, and that of a half-wave retarder is 180°. Circularly polarized light can be generated by passing linearly polarized light through a quarter-wave plate whose axis is at 45° with respect to the incident linear polarization direction. A half-wave plate may change the polarization direction of linearly polarized light. In general, a phase retarder changes linearly polarized light into elliptically polarized light. Representations of the optical response of polarizers, retarders, and other materials in terms of the Müeller matrix and Jones matrix are given in the subsection “Polarization by the Response of a Medium” and also in References 4 through 8 and 12 through 24.

Polarization is generated by the anisotropic response of materials and/or anisotropic geometry of systems. The mechanisms for producing polarization include preferential absorption in a dichroic material, reflection and transmission at oblique incidence, double refraction in a birefringent material, diffraction by grating or wires, and scattering by particles [2–11, 13]. These properties can be utilized to make polarizers and phase retarders. For example, a wire-grid polarizer is made of parallel fine conducting wires. When light is incident on a wire-grid polarizer with the grid period smaller than the wavelength, the electric field parallel to the wires is shorted and absorbed so that only the electric field perpendicular to the wires passes through the polarizer. In a dichroic polarizer, anisotropic molecules are aligned in a preferential direction so that absorption is very different for the two orthogonal directions referred to the alignment direction. The nonpreferential field is absorbed by the molecules in the medium, while the preferential field passes through the medium [5, 8]. In a prism polarizer, the two orthogonal fields are separated by double refraction in a birefringent crystal, and the unwanted polarization is deflected away by the special geometry of a prism. A material is birefringent when it has different refractive indices for different field directions. When a light beam passes through a birefringent slab, a phase retardation is generated. Birefringent slabs can be used to make phase retarders or wave plates. Different kinds of polarizers and retarders are described in detail in References 5 and 9 through 11.

When special arrangements of polarizers and phase retarders are combined with a light source and a detector, polarized light can be generated and analyzed. Such an optical system is called a polarimeter or an ellipsometer. The subsection “Principles of Polarimetry” discusses the generation and analysis of polarized light and the operational principles for Polarizer-Sample-Analyzer (PSA) ellipsometry and...
Polarizer-Compensator-Sample-Analyzer (PCSA) ellipsometry using the intensity approach associated with Stokes vectors and Müllner matrices [4, 17–23, 25, 26]. A phase retarder is also called a compensator because it was introduced into a polarimeter to compensate the phase change by a sample. The intensity approach was chosen because intensity, but not electric field, is measured in most experiments, and also because the electric field approach cannot treat depolarization. However, the electric field approach is convenient to use for highly polarized light when depolarization does not cause appreciable errors in the measurement. Discussion of ellipsometry using the electric field approach can be found in References 4, 15, 16, and 27 through 33.

Polarization effects are widely applied in modern optical technologies. The electro-optic modulator and shutter are based on tunable birefringence by applying a high voltage across a birefringent crystal to modulate the phase of transmitted light and hence to achieve intensity modulation [4, 7, 9, 34, 35]. Liquid crystal displays use similar principles [36]. Birefringence can also be modulated by the photoelastic effect [37, 38]. The magneto-optical readout for laser disks utilizes the magneto-optical Kerr effect that generates phase retardation upon reflection from magnetic materials [34, 39]. Other applications of polarization are fiber optics, nonlinear optics, material characterization, medical optics, and many other fields. All of these applications utilize the anisotropic nature of materials or the anisotropic geometry of systems. This chapter is concerned with the application of polarization on material characterization. In this application, a polarimeter or ellipsometer is used to measure optical properties and surface properties of materials and thin films [40–48, see also Chapter 61, “Refractive Index”]. In the subsection “Polarization Instrumentation and Experiments,” different components of polarimeters are discussed using an example of an automated reflection null ellipsometer, and two sample experiments are described to measure birefringence of a birefringent slab and the optical constants of a material.

60.2 Polarization of an Electromagnetic Wave

The electric field \( \mathbf{E}(z, t) \) of a monochromatic EM wave propagating along the z-direction with a frequency \( \omega \) and an angular wave-number \( k \) can be decomposed into two orthogonal components \( E_x \) and \( E_y \) and represented by

\[
\begin{align*}
\mathbf{E}(z, t) &= \hat{x} E_x(z, t) + \hat{y} E_y(z, t) \\
E_x(z, t) &= a_x e^{i(\omega t - kz + \delta_x)} \\
E_y(z, t) &= a_y e^{i(\omega t - kz + \delta_y)}
\end{align*}
\]

(60.1)

where \( a_x \) and \( \delta_x \) are the amplitude and phase, respectively, for \( E_x \), and \( a_y \) and \( \delta_y \) are for \( E_y \) [1–4]. \( k \) is related to wavelength \( \lambda \) by \( k = 2\pi/\lambda \). In vacuum, \( k = \omega/c \). Let \( \delta = \delta_y - \delta_x \) be the relative phase between \( E_y \) and \( E_x \). Then Equation 60.1 can be simplified to

\[
\mathbf{E}(z, t) = (\hat{x} a_x + \hat{y} a_y e^{i\delta}) e^{i(\omega t - kz + \delta_x)}
\]

(60.2)

Polarization Ellipse

It is often convenient to express \( \mathbf{E} \) in terms of a complex variable. The observed field is actually the real part of \( \mathbf{E} \). The projection of \( \text{Re} \{ \mathbf{E}(z, t) \} \) with \( \delta_y = 0 \) onto the xy-plane at \( z = 0 \) is given by

\[
\mathbf{E}(0, t) = \hat{x} a_x \cos \omega t + \hat{y} a_y \cos (\omega t + \delta)
\]

(60.3)

The loci of \( \mathbf{E}(0,t) \) with \( a_x = 3 \), \( a_y = 2 \) and different values of \( \delta \) are shown in Figure 60.1. For \( \delta = 0 \), the locus of \( \mathbf{E} \) is a line with a slope of \( a_y/a_x \). The EM wave is linearly polarized when \( E_x \) and \( E_y \) are in phase.
with each other. In other cases, the loci are ellipses, which are called polarization ellipses, and the EM wave is elliptically polarized. The instantaneous electric field can be visualized by drawing an arrow from the origin to a point on an ellipse. The electric field direction rotates in the clockwise direction for $0 < \delta < 180^\circ$, while in the counterclockwise direction for $-180 < \delta < 0^\circ$. When $\delta = \pm 90^\circ$, the axes of the ellipse correspond to the $x$ and $y$ coordinate axes. If $a_x = a_y$, this ellipse then becomes a circle, and the EM wave is circularly polarized. The convention in ellipsometry defines the right-handed circularly polarized wave as the one whose field rotates in the clockwise direction with $\delta = 90^\circ$ [4, 5]. A left-handed circularly polarized wave thus corresponds to $\delta = -90^\circ$ for a counterclockwise rotating electric field.

In Figure 60.1, a polarization ellipse is specified by a set of three parameters: $a_x$, $a_y$, and $\delta$. The ellipse can also be specified by the other set of three parameters: the major axis $a$, the minor axis $b$, and the orientation angle $\phi$ of the major axis measured from the $x$-axis. Figure 60.2 shows the geometry of an ellipse with these parameters. Parameters $a$ and $b$ can also be expressed in terms of the ellipticity $e$ and ellipticity angle $\varepsilon$, defined by $e = b/a = \tan \varepsilon$. For linear polarization, $\delta = 0$, $b = 0 = e = \varepsilon$, and $\tan \phi = a_y/a_x$. For $\phi = 0$, the major and minor axes of the ellipse always correspond to the coordinate axes. For circular polarization, $a = b = a_x = a$, and $\delta = \pm 90^\circ$. Right-handed circularly polarized light has a positive ellipticity with $e = 1$ and $\varepsilon = 45^\circ$, and left-handed circularly polarized light has a negative ellipticity with $e = -1$ and $\varepsilon = -45^\circ$. In general, $\phi$ represents the orientation of the ellipse, and $\varepsilon$ indicates the shape of the ellipse and the direction of field rotation. References 2 through 7 give more details about this subject.

### Jones Vector and Stokes Vector

The electric field expressed in vector form in Equation 60.1 can also be expressed as a column matrix. A polarization ellipse depends on $a_x$, $a_y$, $\delta_x$, and $\delta_y$, but not on $k$ and $\omega$. By neglecting the common factor of $e^{i(\omega t - kz)}$ in both $E_x$ and $E_y$, the Jones vector is defined as [4, 7, 8]

![Electric Field on a Plane](image)

**FIGURE 60.1** Projection of the electric field of an EM wave with amplitudes $a_x = 3$, $a_y = 2$ and different values of phase retardation $\delta$ onto the $z = 0$ plane. Most of these loci are ellipses and reduce to lines or circles in special cases. The electric field changes in the clockwise direction for $\delta$ between 0 and 180°.
Both elements of a Jones vector are complex numbers. Jones algebra is convenient for describing perfectly polarized light. Since a light sensor measures only intensity but not electric field in most cases, the Stokes vector is more convenient to use in metrology. The Stokes parameters are four intensity-based parameters used to describe the polarization state of light, represented by $S_0, S_1, S_2, S_3$, or by $I, Q, U, V$ \cite{1, 6, 14}. The Stokes vector is the set of these Stokes parameters, defined as \cite{4, 14}

$$
S = \begin{pmatrix}
S_0 \\
S_1 \\
S_2 \\
S_3
\end{pmatrix} = \begin{pmatrix}
\langle E_x E_x^* \rangle + \langle E_y E_y^* \rangle \\
\langle E_x E_x^* \rangle - \langle E_y E_y^* \rangle \\
\langle E_x E_y^* \rangle + \langle E_y E_x^* \rangle \\
i \langle E_x E_y^* \rangle + i \langle E_y E_x^* \rangle
\end{pmatrix}
$$

(60.5)

For an EM wave, the average bracket in Equation 60.5 represents the time average. $\langle E_x E_x^* \rangle = I_x$ is the intensity of the component of light linearly polarized in the $x$-direction. Similarly, $\langle E_y E_y^* \rangle = I_y$. All of the Stokes parameters are real numbers and are measurable. For an ensemble of EM waves, the average brackets represent both time and ensemble averages.

\[\text{FIGURE 60.2}\] Characteristic parameters for a polarization ellipse. $a_x$ and $a_y$ are the field amplitudes in the $x$- and $y$-directions, and $\delta$ is the phase retardance; $a$ and $b$ are the major and minor axes of the ellipse; $\phi$ is the orientation of the major axis with respect to the $x$-axis, and $\varepsilon$ is the ellipticity angle which is equal to $\tan^{-1}(b/a)$. A polarization ellipse can be characterized by $(a_x, a_y, \delta), (a, b, \phi)$ or $(I, \phi, \varepsilon)$, where $I$ is the intensity of the EM wave.
Perfectly Polarized Light

Stokes vectors for different polarization states of light can be evaluated using Equation 60.5. Table 60.1 lists the Jones vectors and Stokes vectors for different states of perfectly polarized light. The Jones vector \( \mathbf{E} \) and Stokes vector \( \mathbf{S} \) expressed in terms of ellipticity angle \( \varepsilon \) and orientation angle \( \phi \) are

\[
\mathbf{E} = \begin{pmatrix} \cos \varepsilon \cos \phi - i \sin \varepsilon \sin \phi \\ \cos \varepsilon \sin \phi + i \sin \varepsilon \cos \phi \end{pmatrix}
\]

(60.6)

\[
\mathbf{S} = \begin{pmatrix} 1 \\ \cos 2\varepsilon \cos 2\phi \\ \cos 2\varepsilon \sin 2\phi \\ \sin 2\varepsilon \end{pmatrix}
\]

(60.7)

In Equations 60.6 and 60.7, the amplitude \( a \) and intensity \( I \) are totally separated from the angles \( \phi \) and \( \varepsilon \) which determine the polarization state. The degrees of linear and circular polarization are \( \cos 2\varepsilon \) and \( \sin 2\varepsilon \), correspondingly. Stokes parameters for perfectly polarized light given in Equation 60.7 satisfy the identity

\[
S_0^2 = S_1^2 + S_2^2 + S_3^2
\]

(60.8)

60.3 Polarization of Light

Light is composed of an ensemble of EM waves. A single EM wave has a certain electric field direction and phase. Unpolarized light can be visualized as an ensemble of EM waves with random field directions and phases. The field direction and phase for unpolarized light can not be defined then. The description of light in terms of Jones vector is therefore inadequate to describe the polarization of unpolarized light. For an ensemble of many EM waves, the electric field components in the Stokes vector given by Equation 60.5 is the sum of the corresponding components for all waves. In particular, for an ensemble of incoherent EM waves, the Stokes vectors for individual waves are additive:

\[
\mathbf{S} = \sum_{i=1}^{N} \mathbf{S}_i
\]

(60.9)

<table>

<td>( \begin{pmatrix} 1 \ 1 \ 0 \ 0 \end{pmatrix} )</td>
</tr>
</tbody>
</table>
For an ensemble of EM waves with identical $\phi_i = \phi$ and $\varepsilon_i = \varepsilon$, the resultant polarization is still the same as the individual wave, as indicated by Equations 60.6 and 60.7, regardless of whether these waves are coherent.

Unpolarized and Partially Polarized Light

If an ensemble consists of randomly oriented linearly polarized waves, all $\varepsilon_i = 0$ and $\phi_i$ are random, then $S_1 = S_2 = S_3 = 0$, according to Equations 60.7 and 60.9. Light is thus unpolarized, and $S = I(1, 0, 0, 0)$. If an ensemble consists of elliptically polarized waves with the same orientation $\phi_i = \phi$ or $\phi + \pi$ and perfectly random ellipticity angle $\varepsilon_i$, then the Stokes vector is $I(1, 0, 0, 0)$, and light is also unpolarized. Thus, the Stokes vector $S$ in Equation 60.9 already implies the sense of the ensemble average of polarization. The average brackets in Eq. (5) can be considered as both the time average and ensemble average for incoherent waves.

For unpolarized light with $S_1 = S_2 = S_3 = 0$, Equation 60.8 does not hold. In general, light is partially polarized, i.e., part of it is perfectly polarized and the rest is unpolarized [1–6]. Stokes parameters for arbitrary polarizations satisfy

$$S_0^2 \geq S_1^2 + S_2^2 + S_3^2 \quad (60.10)$$

The degree of polarization is given by

$$P = \frac{\sqrt{S_1^2 + S_2^2 + S_3^2}}{S_0} \quad (60.11)$$

Perfectly polarized light has $P = 1$, and unpolarized light has $P = 0$. Partially polarized light has $0 < P < 1$.

The intensity of the polarized part is $P I$, and the intensity of the unpolarized part is $I(1 - P)$. By the superposition concept, the Stokes vector for partially polarized light can be obtained from Equation 60.7 as

$$S = I \begin{pmatrix} 1 \\ P \cos 2\varepsilon \cos 2\phi \\ P \cos 2\varepsilon \sin 2\phi \\ P \sin 2\varepsilon \end{pmatrix} \quad (60.12)$$

The degree of linear polarization $P_L$ and circular polarization $P_C$ are

$$P_L = P \cos 2\varepsilon = \frac{\sqrt{S_1^2 + S_2^2}}{S_0} \quad (60.13)$$

$$P_C = P \sin 2\varepsilon = \frac{S_3}{S_0}$$

Polarization by the Response of a Medium

Jones Matrix

To measure polarization, light must interact with a medium to give a response. The response of a polarizer is to pass one polarization and reject the orthogonal one. The response of a phase retarder is to change
the relative phase between the two polarizations. A medium can be any optical component, a test sample or any object under investigation. The response of a medium relates the state of output light to the state of incident light. The polarization state of light can be described by a complex vector EM field, a Jones vector, or a Stokes vector \[4, 5, 7, 8\]. Let an incident EM wave be specified by a complex field or Jones vector \((E_x, E_y)\), and the output field be \((E_x', E_y')\), the general relations between these two fields are

\[
\mathbf{E}' = \begin{pmatrix} E_x' \\ E_y' \end{pmatrix} = \begin{pmatrix} r_{xx} & r_{xy} \\ r_{yx} & r_{yy} \end{pmatrix} \begin{pmatrix} E_x \\ E_y \end{pmatrix} = \mathbf{J} \mathbf{E} \tag{60.14}
\]

\(\mathbf{J}\) in Equation 60.14 is a \(2 \times 2\) matrix that relates the input Jones vector \(\mathbf{E}\) to the output Jones vector \(\mathbf{E}'\) and is called the Jones matrix. The response of a medium is characterized by the elements of the Jones matrix, \(r_{xx}, r_{xy}, r_{yx},\) and \(r_{yy}\) which are all complex numbers.

**Principal Coordinate System**

Since the directions of an electric field are different in different rotated coordinate systems, \(\{r_{ij}\}\) are not unique. For many symmetric media, there exists a coordinate system in which \(r_{xy}\) and \(r_{yx}\) are zero, and \(r_{xx}\) and \(r_{yy}\) are called the eigenvalues for \(\{r_{ij}\}\). This is the principal coordinate system or principal frame whose \(x\)- and \(y\)-axes are the two principal axes. Finding the principal frame is an eigenvalue problem. If the incident polarization is along one of the principal-axis \(\hat{x}\), then the output polarization is still along \(\hat{x}\). In the principal frame, \(\{r_{ij}\}\) are called the coefficients of response. For example, \(\{r_{ij}\}\) may represent the reflection coefficients for a reflection response, or the scattering coefficients for a scattering response, etc. In the principal coordinate system, Equation 60.14 is simplified to

\[
\mathbf{E}' = \begin{pmatrix} E_x' \\ E_y' \end{pmatrix} = \begin{pmatrix} r_{xx} & 0 \\ 0 & r_{yy} \end{pmatrix} \begin{pmatrix} E_x \\ E_y \end{pmatrix} = \mathbf{J}(0)\mathbf{E} \tag{60.15}
\]

\(\mathbf{J}(0)\) is the diagonalized Jones matrix in the principal frame. For a polarizer, the principal axes are the transmission and extinction axes. The former is assigned to the \(x\)-axis. For a phase retarder, the principal axes are the fast- and slow-axes. The phase change for the EM wave with its field along the fast-axis is larger than the slow-axis. The fast-axis is usually assigned to the \(x\)-axis. The principal Jones matrices \(\mathbf{p}\) for a perfect polarizer, and \(\mathbf{c}\) for a perfect wave plate with a retardance \(\tau\) are \[4, 5, 7, 8\]

\[
\mathbf{p} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad \mathbf{c} = \begin{pmatrix} e^{i\tau/2} & 0 \\ 0 & e^{-i\tau/2} \end{pmatrix} \tag{60.16}
\]

**Ellipsometric Parameters**

For reflection from a surface, the two principal axes are the \(s\)- and \(p\)-polarizations. The \(s\)-polarization field is along the \(y\)-axis which is chosen to be perpendicular to the plane of incidence. The \(p\)-polarization field is along the \(x\)-axis which is in the plane of incidence. The complex reflection coefficients for these two polarizations are designated as \(r_p = r_{xx}\) and \(r_s = r_{yy}\). The ellipsometric parameters \(\psi\) and \(\Delta\) are defined by \[4, 15, 16\]

\[
\frac{r_p}{r_s} = \frac{r_{xx}}{r_{yy}} = \tan\psi \exp(i\Delta) \tag{60.17}
\]
\( \Delta \) is the phase change between reflected and incident light. If the electric field direction of incident light is given by \( \phi \), then the field direction \( \phi \) of reflected light can be obtained from \( \tan \phi = \tan \phi_0 / \tan \psi \). At the Brewster angle, where \( r_p = 0 \) and \( \psi = 0 \), then \( \phi = 90^\circ \), and reflected light is vertically polarized. Equation 60.17 can also be applied to transmissive systems. Since a vacuum does not change the polarization of light, the ellipsometric parameters are \( \psi = 45^\circ \) and \( \Delta = 0^\circ \). A perfect polarizer with the polarization along the \( x \)-axis has \( \psi = 90^\circ \) and \( \Delta = 0^\circ \), a perfect quarter-wave plate has \( \psi = 45^\circ \) and \( \Delta = 90^\circ \), and a perfect half-wave plate has \( \psi = 45^\circ \) and \( \Delta = 180^\circ \).

**Müeller Matrix**

The Jones calculus is convenient for perfectly polarized light and a nondepolarizing response [8]. If unpolarized light is incident on a sample, the Jones vector cannot describe the field direction and phase for unpolarized light. The Stokes vector and Müeller matrix are more convenient to use in treating polarization for general cases. A relation between the output Stokes vector \( \mathbf{S} \) and the input Stokes vector \( \mathbf{S} \) is

\[
\mathbf{S'} = \mathbf{M} \mathbf{S}
\]

(60.18)

The matrix \( \mathbf{M} \) that relates the input and output Stokes vectors is called a Müeller matrix. \( \mathbf{M} \) is a \( 4 \times 4 \) matrix of real numbers.

For the general transformation of electric field given by Equation 60.14, the components \( M_i \) of \( \mathbf{M} \) can be derived from Equations 60.5, 60.14, and 60.18. The expressions for \( M_i \) have been obtained by van de Hulst [13] and are also given as Equation (2.243) of Reference 4. In a measurement, the EM waves of output light may come from many different area or volume elements of a medium, so that statistical averages must be considered in the evaluation of \( M_i \). The ensemble average of \( \mathbf{M} \) can still be expressed by the same expressions, with the ensemble average bracket applying to all \( M_i \). To make the Müeller matrix meaningful, the new subscripts of Equation 60.14 are reassigned as 1: \( xx \), 2: \( yy \), 3: \( xy \), 4: \( yx \). Subscripts 1 and 2 correspond to the copolarized response, and subscripts 3 and 4 correspond to the cross-polarized response. The ensemble average of any two of the response coefficients is called a correlation function for these coefficients. Let us define the self-correlation functions to be \( 2 F_j \) and the cross-correlation functions to be \( G_{jm} + i g_{jm} \) as follows:

\[
\begin{align*}
2 F_j &= \langle r_j r^*_j \rangle \\
G_{jm} + i g_{jm} &= \langle r_j r^*_m \rangle
\end{align*}
\]

(60.19)

The cross-correlation functions have the properties of \( G_{jm} = G_{mj} = \text{Re} \langle r_j r^*_m \rangle \), and \( g_{jm} = -g_{mj} = \text{Im} \langle r_j r^*_m \rangle \). All \( F_j \), \( G_{jm} \), and \( g_{jm} \) are real numbers. \( \mathbf{M} \) is then

\[
\mathbf{M} = \begin{pmatrix}
F_1 + F_2 + F_3 + F_4 & F_1 - F_2 - F_3 + F_4 & G_{13} + G_{24} & g_{13} - g_{24} \\
F_1 - F_2 + F_3 - F_4 & F_1 + F_2 - F_3 - F_4 & G_{13} - G_{24} & g_{13} + g_{24} \\
G_{14} + G_{23} & G_{14} - G_{23} & G_{12} + G_{34} & g_{12} - g_{34} \\
-g_{14} + g_{23} & -g_{14} - g_{23} & -g_{12} - g_{34} & G_{12} - G_{34}
\end{pmatrix}
\]

(60.20)

The upper left quadrant of \( \mathbf{M} \) corresponds to the self-correlation terms. The lower right quadrant corresponds to the cross-correlations between the two co-polarized responses and between the two cross-polarized responses. The upper right and lower left quadrants correspond to the cross-correlations between the co-polarized and cross-polarized responses.
Principal Müeller Matrix

For the Jones matrix in the principal frame given by Equation 60.15, the cross-polarized responses are zero, so that the $M_{jm}$ in the upper right and lower left quadrants of Equation 60.20 are zero. $M$ can be expressed in terms of $\psi$ and $\Delta$ using Equations 60.17 and 60.20 as

\begin{equation}
M = R \begin{pmatrix}
1 & -\cos 2\psi & 0 & 0 \\
-\cos 2\psi & 1 & 0 & 0 \\
0 & 0 & \sin 2\psi \cos \delta & \sin 2\psi \sin \Delta \\
0 & 0 & -\sin 2\psi \sin \Delta & \sin 2\psi \cos \Delta \\
\end{pmatrix} \tag{60.21}
\end{equation}

where $R = (r_{xx} r_{xx}^* + r_{yy} r_{yy}^*)/2$. For reflection, $R$ is the average reflectance, and for transmission, $R$ is the average transmittance. For a vacuum, $\psi = 45^\circ$ and $\Delta = 0^\circ$, $M$ is a unit matrix. Using Equation 60.21 or Equations 60.16, 60.19, and 60.20 directly, matrix $P$ for a perfect polarizer ($\psi = 90^\circ$, $\Delta = 0^\circ$) and matrix $C$ for a perfect wave plate ($\psi = 45^\circ$, $\Delta = \tau$) in the principal frame are obtained as

\begin{equation}
P = \frac{1}{2} \begin{pmatrix}
1 & 1 & 0 & 0 \\
1 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
\end{pmatrix} \quad \text{C} = \begin{pmatrix}
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & \cos \tau & \sin \tau \\
0 & 0 & -\sin \tau & \cos \tau \\
\end{pmatrix} \tag{60.22}
\end{equation}

Depolarization

A very interesting example is the perfectly random response. Analogous to the conditions used for incoherent scattering [17–19], the random response coefficients $\delta r_j$ have the properties that

\begin{align*}
\langle \delta r_j \rangle &= 0 \\
\langle \delta r_j \delta r_m^* \rangle &= \langle |\delta r_j|^2 \rangle \delta_{jm} \quad j,m = 1,2,3,4 \\
\langle |\delta r_j|^2 \rangle &= \text{constant}
\end{align*} \tag{60.23}

The first line states that all $\delta r_j$ are each averaged to zero, so that they would not appear in the average of Equation 60.14. By substitution of $r_j$ of Equation 60.19 by $\delta r_j$ and using the conditions for $\delta r_j$ given by Equation set 60.23, the correlation functions $F_j$ and $G_{jm} + i g_{jm}$ can be evaluated. The second line of Equation set 60.23 states that all $\delta r_j$ are uncorrelated with one another, so that all $G_{ji}$ and $g_{ji}$ are zero. The third line states that $\delta r_j$ are isotropic, so that all $F_j$ are the same. Eventually, all $M_{jm} = 0$ except $M_{00} = 4 F_c$. The depolarization matrix $D$ for a perfectly random response is then

\begin{equation}
D = \begin{pmatrix}
1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
\end{pmatrix} \tag{60.24}
\end{equation}

$D$ is an ideal depolarizer as defined in Reference 20. The general Müeller matrix of Equation 60.20 satisfies the physical condition [14, 24]

\begin{equation}
\sum_{i,j=0}^{3} M_{ij}^2 \leq 4 M_{00}^2 \tag{60.25}
\end{equation}
The sum of all the squares of the elements of $D$ is $M_{00}^2$. $D$ satisfies the inequality of criterion in Equation 60.25. The matrix of Equation 60.21 is nondepolarizing such that output light is still perfectly polarized if incident light is perfectly polarized. The equality in Equation 60.25 holds for $M$ of Equation 60.21. This section discusses optical components and samples that are nondepolarizing. References 12 and 17 through 19 give more details about the Müeller matrices for samples that exhibit both polarization and depolarization properties.

**Coordinate Transformation**

In polarimetric measurements, polarizers and retarders are frequently rotated to desired positions. When a component is rotated, the incident field is not changed, but the representations of this field in the principal and laboratory coordinate systems are different. Transformations of the electric fields, Stokes vectors, Jones and Müeller matrices between these two coordinate systems or frames are basic exercises in polarimetry. Let the laboratory frame axes be $x$- and $y$-axes, and the principal frame axes be $x'$- and $y'$-axes, and the principal frame is rotated to an angle $\alpha$ with respect to the laboratory frame, as shown in Figure 60.3. The Jones vector $(E'_x, E'_y)$ in the principal frame is related to $(E_x, E_y)$ in the laboratory frame by

$$E' = \begin{pmatrix} E'_x \\ E'_y \end{pmatrix} = \begin{pmatrix} \cos \alpha & \sin \alpha \\ -\sin \alpha & \cos \alpha \end{pmatrix} \begin{pmatrix} E_x \\ E_y \end{pmatrix} = r(\alpha)E$$

(60.26)

The rotation matrix $r(\alpha)$ is the $2 \times 2$ matrix in Equation 60.26 for transformation of Jones vectors. The inverse transform is given by $E = r^T(\alpha) E'$, where the superscript $T$ denotes the transpose of a matrix. In Figure 60.3, $E'$ appears to be turned by an angle of $-\alpha$, since the coordinate system is rotated by an angle $\alpha$. The Faraday rotation matrix that rotates $E$ by an angle of $\alpha$ is equivalent to $r(\alpha)$.

One can substitute $r_1 = r_2 = \cos \alpha$ and $r_3 = -r_4 = \sin \alpha$ into Equations 60.19 and 60.20 to construct the rotation matrix $R(\alpha)$ for transformation of a Stokes vector $S$ to a coordinate system oriented at an angle $\alpha$.

$$R(\alpha) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos 2\alpha & \sin 2\alpha & 0 \\ 0 & -\sin 2\alpha & \cos 2\alpha & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

(60.27)

**FIGURE 60.3** Coordinate transformation for the electric field components $(E_x, E_y)$ in the laboratory system $(x, y)$ and the components $(E'_x, E'_y)$ in the principal coordinate system $(x', y')$. The principal frame is oriented at an angle $\alpha$ with respect to the laboratory frame.
The transformations between Stokes vector $S$ in the principal frame and $S$ in the laboratory frame are

$$
S' = R S \\
S = R^T S'
$$  \hspace{1cm} (60.28)

The transformation of a Müeller matrix $M(0)$ in the principal frame to $M(\alpha)$ in the laboratory frame can be obtained by a similarity transformation:

$$
M(\alpha) = R^T(\alpha)M(0)R(\alpha)
$$  \hspace{1cm} (60.29)

Equation 60.29 can also be used for the transformation of Jones matrix $J(0)$ in the principal coordinate frame to $J(\alpha)$ in the laboratory frame, provided that $M$ is replaced by $J$ and $R(\alpha)$ by $r(\alpha)$ in Equation 60.29.

The Jones matrix for a polarimetric component orientated at an angle $\alpha$ is

$$
J(\alpha) = \begin{pmatrix}
    r_{xx} \cos^2 \alpha + r_{yy} \sin^2 \alpha & \sin \alpha \cos \alpha (r_{xx} - r_{yy}) \\
    \sin \alpha \cos \alpha (r_{xx} - r_{yy}) & r_{xx} \sin^2 \alpha + r_{yy} \cos^2 \alpha
\end{pmatrix}
$$  \hspace{1cm} (60.30)

The Müeller matrix $P(P)$ for a perfect polarizer oriented at an angle $P$ and $C(C)$ for a perfect compensator with a retardance $\tau$ at an angle $C$ are [4, 6, 21]

$$
P(P) = \frac{1}{2} \begin{pmatrix}
1 & \cos 2P & \sin 2P & 0 \\
\cos 2P & \cos^2 2P & \sin 2P \cos 2P & 0 \\
\sin 2P & \sin 2P \cos 2P & \sin^2 2P & 0 \\
0 & 0 & 0 & 0
\end{pmatrix}
$$  \hspace{1cm} (60.31)

$$
C(C) = \begin{pmatrix}
1 & 0 & 0 & 0 \\
0 & \cos^2 2C + \sin^2 2 \cos \tau & \sin 2C \cos 2(1 - \cos \tau) & -\sin 2C \sin \tau \\
0 & \sin 2C \cos 2C(1 - \cos \tau) & \sin^2 2C + \cos^2 2 \cos \tau & \cos 2C \sin \tau \\

\end{pmatrix}
$$  \hspace{1cm} (60.32)

Equations 60.16, 60.22, and 60.30 through 60.32 can be used to calculate the Jones matrices and Müeller matrices for polarizers and wave plates at arbitrary orientations. Table 60.2 lists some of these matrices for the most frequently used devices.

For a light beam passing through successive components orientated at different angles, Müeller matrices or Jones matrices in the laboratory frame must be used for successive multiplications. According to Equation 60.18, the matrix $M_1(\alpha_1)$ for the component that light first passes through should be placed at the extreme right, and the matrix $M_n(\alpha_n)$ for the last component at the extreme left. The combined matrix $\mathbf{M}$ is

$$
\mathbf{M} = M_n(\alpha_n) \cdots M_1(\alpha_1)
$$  \hspace{1cm} (60.33)
60.4 Principles of Polarimetry

Polarimetry is a method for measuring the polarization of light and the polarization response of materials. An optical system used for such purposes is called a polarimeter or an ellipsometer. To measure the polarization response of a sample, polarized light is generated and incident on the sample. By examining the polarization states of both incident and reflected or transmitted light, the characteristics of a sample can be determined. A schematic diagram of a polarimeter used to measure the polarization response of a sample is shown in Figure 60.4. The light source and polarizer are used to generate polarized light, and the analyzer and detector are used to analyze the polarization of light [4, 20]. An analyzer is a polarizer used to analyze polarized light.

Analysis of Polarized Light

Measurement of polarization of light is essential in polarimetry, since polarized light to be examined is not limited to that generated in a laboratory. The instrument to measure the four Stokes parameters is called a photo-polarimeter or a Stokesmeter. To measure linear polarization, pass the light beam through a linear analyzer oriented at angle \( A = 0^\circ, 90^\circ, \) and \( \pm 45^\circ \), and measure the corresponding intensities \( I_x, I_y, I_+ \) and \( I_– \). To measure circular polarization, first pass the light beam through a quarter-wave retarder with \( C = 0^\circ \), then through an analyzer oriented at \( A = \pm 45^\circ \), and measure the intensities \( I_R \) and \( I_L \). The pair of quarter-wave retarder and analyzer constitutes a circular analyzer. A detector measuring intensity corresponds to an operation given by a row vector \( \mathbf{I} = (1, 0, 0, 0) \). The combined operation of a detector following an analyzer is \( \mathbf{IA} = 0.5 (1, \cos 2A, \sin 2A, 0) \). The operations for the linear and circular analyzers on a Stokes vector \( \mathbf{S} \) and the intensities obtained are given in Table 60.3. The Stokes parameters can be obtained from the difference and sum of the intensities for these pair operations, and are given by

\[
\mathbf{S} = \begin{pmatrix} S_0 \\ S_1 \\ S_2 \\ S_3 \end{pmatrix} = \begin{pmatrix} I_x + I_y \\ I_x - I_y \\ I_+ - I– \end{pmatrix}
\]  

(60.34)

Equation 60.34 is a general expression that is good for any polarization states and is also the operational principle for most Stokesmeters. The four-detector Stokesmeter designed by Azzam is an exception that contains no moving components and can measure the four Stokes parameters in real time [26].

Generation of Polarized Light

Characterization of polarization response of a sample requires incident polarized light whose polarization state is controllable. A convenient source is a laser, which may be constructed to emit polarized light directly without the help of extra devices. A half-wave plate may be used to rotate the laser polarization

</table>
to a desired direction by placing the fast-axis bisecting the new and old directions, as shown in Figure 60.5a. Light generated from a lamp and a monochromator is usually partially polarized [12]. To generate linearly polarized light at an angle $P$, a linear polarizer oriented at an angle $P$ is placed behind the monochromator as shown in Figure 60.5b. To generate circularly polarized light, first generate linearly polarized light, and then put a quarter-wave plate behind with the fast-axis oriented at an angle of 45° or −45° with respect to the linear polarization as shown in Figure 60.5c. Such a combination of polarizer and quarter-wave plate is called a circular polarizer. When a phase retarder has an arbitrary retardance or is placed at an arbitrary angle relative to the polarizer, elliptically polarized light is then generated. Given an incident Stokes vector of $(S_0, S_1, S_2, S_3)$, the Stokes vector $S'$ for polarized light generated by the polarizers mentioned above can be obtained from Equations 60.18 and 60.31 through 60.33. The obtained $S'$ are listed in Table 60.4. Note that $S'$ is not directly proportional to $S_0$ unless incident light is unpolarized. Care must be taken in generating polarized light in an ellipsometer because incident light is rarely completely unpolarized.

**Polarizer–Sample–Analyzer Ellipsometry**

An ellipsometer is an instrument to measure the ellipsometric parameters $\psi$ and $\Delta$ of a sample. It can be used for both reflection and transmission. An ellipsometer is usually referred to as the reflection system, and a polarimeter as the transmissive system [4]. Different ellipsometers are designed to measure different responses for different kinds of samples. It is important to know about the sample when designing an experiment. The simplest ellipsometer is a polarizer–sample–analyzer (PSA) ellipsometer. A more general one is a polarizer–compensator–sample–analyzer (PCSA) ellipsometer. Figure 60.6 shows

![FIGURE 60.5](image)

**FIGURE 60.5** Generation of light linearly polarized at a desired direction using (a) a laser source and a half-wave plate and (b) a lamp, monochromator, and a polarizer, plus (c) generation of circularly polarized light using a polarizer and a quarter-wave plate.
a schematic diagram of a PCSA reflection ellipsometer. A PSA system can be visualized by removing the compensator $C$ in Figure 60.6.

Let the oriented angles of the polarizer and analyzer be $P$ and $A$, respectively, as measured from the plane of incidence. For unpolarized incident light and a sample matrix $M$ given by Equation 60.21, the measured intensity $I$ for a PSA ellipsometer is

$$I = T_p T_a R I_0 \left[ 1 - \cos 2 \psi (\cos 2P + \cos 2A) \right] + \cos 2P \cos 2A + \sin 2 \psi \cos \Delta \sin 2P \sin 2A$$

(60.35)

$I_0$ is the intensity of incident light, $T_p$ and $T_a$ are the transmittance of the polarizer and analyzer, respectively. If incident light is partially polarized with a Stokes vector $(S_0, S_1, S_2, S_3)$, then the right-hand side of Equation 60.35 should be multiplied by the factor \( \frac{S_0 + S_3}{2} \). In such a case, the dependence on $P$ is more complicated. A good practice is to keep $P$ fixed and vary only $A$. Many different ways can be devised to extract $\psi$ and $\Delta$ from Equation 60.35, such as the Stokes polarimeter, null polarimeter, and rotating-analyzer ellipsometer.

For a Stokes polarimeter, $P$ is set at $45^\circ$ or $-45^\circ$, and $A$ at $0^\circ$, $90^\circ$, and $\pm 45^\circ$. The ellipsometric parameters $\psi$ and $\Delta$ can be solved from the four equations evaluated at these $P$ and $A$ positions via the relations
For a null polarimeter, set \( P = \pm 45^\circ \), and vary \( A \) to find the null positions. This method is excellent for reflection from transparent materials with \( \Delta \) equal to 0 or \( \pi \). The value of \( \psi \) is related to the null position \( A_{\pm} \) as \[ 60.36 \]

\[
\cos 2\psi = \frac{I_y - I_x}{I_y + I_x} \\
\sin 2\psi \cos \Delta = \frac{I_y - I_-}{I_y + I_-}
\]

Average of \( A_{\pm} \) at \( P = \pm 45^\circ \) can eliminate errors from the misalignment of analyzer and polarizer.

In a rotating-analyzer ellipsometer (RAE), the analyzer is rotated at an angular frequency \( \omega \), Set \( P = 45^\circ \) or \(-45^\circ \), and \( A = \omega t \). The measured intensity is

\[ 60.38 \]

\[
I = T_p R T_a I_0 [1 - \cos 2\psi \cos 2\omega t + \sin 2\psi \cos \Delta \sin 2\omega t]
\]

The Fourier coefficients, being equal to \(-\cos 2\psi \) and \( \sin 2\psi \), can be recovered from the demodulated signals or from a fast Fourier transform (FFT) technique [28, 29]. However, the measured \( \Delta \) cannot be distinguished from \(-\Delta \). This system can be fully automated for realtime operation. With a white light source and monochromator, an RAE can serve as a spectroscopic ellipsometer [15, 16, 28, 29].

### Polarizer–Compensator–Sample–Analyzer Ellipsometry

In a PCSA or a PSCA ellipsometer, a compensator of retardance \( \tau \) is inserted in front of or following the sample. Figure 60.6 shows a schematic diagram of a PCSA ellipsometer. For unpolarized incident light in a PCSA system, the measured intensity for general conditions of \( P, C, \) and \( A \) is given by \[ 60.39 \]

\[
I(P, C, A) = I A(A) M(R, \psi, \Delta) C(C) P(P) S
\]

\[ = T_p R T_a I_0 [Y_0 + Y_1 \cos 2A + Y_2 \sin 2A]
\]

where

\[
Y_0 = [1 - \cos 2\psi [\cos 2C \cos 2(P - C) - \cos \tau \sin 2C \sin 2(P - C)]] \\
Y_1 = [-\cos 2\psi + [\cos 2C \cos 2(P - C) - \cos \tau \sin 2C \sin 2(P - C)]] \\
Y_2 = \sin 2\psi [\cos \Delta [\sin 2C \cos 2(P - C) + \cos \tau \cos 2C \sin 2(P - C)] - \sin \tau \sin \Delta \sin 2(P - C)]
\]

If incident light is partially polarized, then \( I_0 \) in Equation 60.39 should be replaced by \((S_p + S_i \cos 2P + S_i \sin 2P)\). For a PCSA system, interchange \( P \) and \( A \) in Equations 60.39 and 60.40. These formulas can be used to design different kinds of PCSA ellipsometers by choosing different conditions and different types of modulation. For certain special conditions, Equations 60.40 can be greatly simplified.

### Null Ellipsometry

Consider a PCSA null ellipsometer (NE) in which the compensator is a perfect quarter-wave retarder \((\tau = 90^\circ)\) which is set at \( C_{\pm} = \pm 45^\circ \). The measured intensity is

\[
\tan 2A_{\pm} = \mp \tan 2\psi \cos \Delta \quad \text{for} \quad P = \pm 45^\circ
\]

\[ 60.37 \]
An NE is an instrument to find the null positions in order to determine $\psi$ and $\Delta$. The four zones that will null the intensity in Equation 60.41 and the null positions are listed in Table 60.5. The null positions of $A$ give $\psi$ directly, and the null positions of $P$ give $\Delta$ directly. Although $\psi$ and $\Delta$ can be determined from measurements in only one zone, systematic errors caused by imperfect components, misalignment, and partially polarized incident light can be nonnegligible. By taking the average of four zones, many of these linear systematic errors can be cancelled [4, 21, 30, 31]. To look for the null positions manually is a slow process; automation of the nulling process can speed up the measurements. Different methods can be used to automate the NE: (1) both polarizer and analyzer are controlled by servo-motors with the feedback from the detector to find the null intensity, (2) the intensity is digitized and fed into a computer which is used to find the null positions, (3) Faraday rotators are used to rotate and modulate the polarization directions of light incident on and reflected from the sample to get the slopes of intensity versus angle until the slopes are zero at the null positions [4, 27]. The advantage of NE is its simplicity in obtaining $\psi$ and $\Delta$. Also, its accuracy is unbeatable by other kinds of ellipsometry.

### Phase-Modulated Ellipsometry

A phase-modulated ellipsometer (PME) uses a phase retarder whose retardance is modulative. For a PME, a good choice of $P$, $C$, and $A$ in Equations 60.39 and 60.40 is $P = 0^\circ$, $C = 45^\circ$, and $A = 45^\circ$. The intensity is then

$$I(\tau) = T_p T_c R T_a I_0 [1 - \cos 2\psi \cos 2\Delta \cos\Delta \sin 2\psi \sin 2\Delta \sin (2\psi - 90^\circ)]$$  \hspace{1cm} (60.42)$$

The retardance $\tau$ is modulated, and the modulated intensity is detected. If $\tau$ is modulated according to $\tau = \tau_0 \cos \Omega t$, then $I(\tau)$ can be expanded in a Fourier series with the Fourier coefficients, depending on $\cos 2\psi$, $\sin 2\psi \cos \Delta$ and the Bessel functions of $\tau_0$. These coefficients can be recovered from the demodulated signals, and the values of $\psi$ and $\Delta$ can then be solved. $\tau$ can be modulated by electro-optic modulation using the Pockels effect, or piezoelectric modulation using the photoelastic effect [32, 33]. These modulations are fast, and demodulation using a lock-in amplifier is convenient. The advantage of a PME is that it contains no moving components and offers real-time measurement.

### 60.5 Polarization Instrumentation and Experiments

**Figure 60.7** shows a schematic diagram of a PCSA reflection null ellipsometer. The instrument is composed of five systems: the source system, polarimetric system, sample system, detection system, and computer system for automatic control, data acquisition, and processing.

The simplest source is a polarized laser. The monochromatic source system in Figure 60.7 is usually used in visible, ultraviolet and infrared spectrometers. Light from a lamp source L is focused by a lens system or a spherical mirror system onto the entrance slit of a grating monochromator M. Light leaving...
the exit slit of M is collimated by another lens system and a set of iris apertures. The long-pass filter F in the detector arm is used with a grating monochromator to remove undesired short-wavelength radiation. Choices of monochromators include a grating monochromator, prism monochromator or Fourier transform spectrometer. A spectrometer is a necessary component for a spectroscopic ellipsometer. Synchrotron radiation is also a continuum source and is used to replace the lamp in the vacuum ultraviolet region [25]. The synchrotron radiation beam is intense and polarized. Grazing incidence reflection optics are usually used to avoid absorption in the components.

The polarimetric system shown in Figure 60.7 is a PCSA ellipsometer. For a PSA ellipsometer, remove the compensator C. For a PCSCA system, add another compensator in the detector arm [20]. It is better to mount the polarizers and phase retarders on automatic rotators so that their orientations can be easily aligned and read. For simple experiments, manual rotators can also do the job. References 10 and 11 give detailed descriptions and references for different kinds of polarizers and phase retarders. Many of the well known optical companies sell polarizers and wave plates (retarders) for use in the visible, ultraviolet, and near infrared spectral regions. The Buyers Guide of Laser Focus World [49] and the Photonics Buyers' Guide [50] list companies that manufacture and sell polarizers, phase retarders and polarimeters. Tables 60.6 and 60.7 list some companies that make these products. Commonly used polarizers in the visible are Glan prisms and dichroic sheets or plates. The best polarizer in the visible is the calcite Glan-Thompson prism, which has a very small extinction ratio and a large acceptance angle. It is more difficult to find a good broadband polarizer in the mid-infrared spectral region (λ: 3 to 5 µm). Wire-grid polarizers are good in the long-wave infrared region (λ > 8 µm). For a broadband phase retarder, a Babinet-Soleil compensator is convenient, since it can be set to any retardance value using a micrometer adjustment. Inexpensive wave plates are good for laser sources. Phase modulation can be achieved by modulation of the birefringence of electro-optic or photo-elastic retarders.

The sample system depends on the type of experiment to be performed. Components on the detector side of Figure 60.7 are normally mounted on a rail that is rotatable about the axis of the rotation stage. The sample holder S on the rotation stage should have enough degrees of freedom for easy alignment. In a reflection ellipsometer, the x-axes for P, C, and A should be well aligned to lie in the plane of incidence. A transmission polarimeter is much simpler to align.

The detection system consists of a detector and a noise suppression system. Diode detectors for use in the visible and near-infrared spectral regions are inexpensive. Photomultipliers for the visible and
near-infrared regions have high sensitivity, and cooled semiconductor detectors give good performance in the mid-infrared to far-infrared regions. In Figure 60.7, the noise suppression system includes a chopper and a lock-in amplifier. The chopper modulates incident light intensity, and the intensity detected by detector D is demodulated by a lock-in amplifier. This combination eliminates most broadband noise and greatly improves the signal-to-noise ratio. RAE and PME have their own modulations, and do not need a chopper.

A computer system provides the automatic functions to control the polarizers, retarder, and monochromator, and to acquire and process data. A computer system is essential for making accurate and rapid measurements. In Figure 60.7, the computer records the polarizer angle \( P \), the analyzer angle \( A \), the intensity \( I \) from the detector, and the wavelength \( \lambda \) of the monochromator. The data of \( I(P) \) and \( I(A) \) can be used to find the null positions of \( P \) and \( A \). Then the computer controls the drivers to move \( P \) or \( A \) to the null positions. In a spectroscopic RAE, data of \( I(t) \) are recorded as the analyzer is rotating. The computer uses the FFT program to find the Fourier coefficients, solves for \( \psi \) and \( \Delta \), records the results, and then drives the monochromator to a new wavelength and repeats the process. A spectroscopic PME uses similar computer process as RAE, besides the different modulation and demodulation.

**Measurement of Birefringence**

Retardance can be measured using a transmission PSA ellipsometer. A wave plate is a good sample for this experiment. The retardance \( \delta \) for a birefringent slab of thickness \( d \) and principal refractive indices \( n_e \) and \( n_o \) is

\[
\delta = \frac{2\pi d(n_e - n_o)}{\lambda} \tag{60.43}
\]

in the absence of multiple reflections. For a wave plate, the value of \( \psi \) is close to 45°, and the \( \Delta \) value is equal to \( \delta \). Use a lamp source with a monochromator to scan the wavelength. Put a polarizer at 45° and an analyzer at –45° with respect to the fast-axis of the wave plate [40]. When \( \lambda \) is scanned, the transmitted intensity \( I \) through the PSA ellipsometer will vary, in proportion to \((1 + \cos \delta)\) according to Equation 60.35. \( I \) is a maximum when \( \delta = 0^\circ \), and is a minimum when \( \delta = 180^\circ \). From the wavelengths at which a maximum or a minimum intensity occurs, the birefringence \( n_e - n_o \) can be determined.

**Measurement of Optical Constants**

A reflection ellipsometer can be used to measure optical constants \( n \) and \( k \) of materials. Light is incident obliquely on a sample at an angle of \( \theta \). The refractive index \( n \) and the extinction coefficient \( k \) can be calculated from the measured \( \psi \) and \( \Delta \) values using the following formula [2, 4, 16, 22]

\[
(n + ik)^2 = \sin^2 \theta \left[ 1 + \tan^2 \theta \left( \frac{1 - \tan \psi \exp(i\Delta)}{1 + \tan \psi \exp(i\Delta)} \right)^2 \right] \tag{60.44}
\]

If an automated system is not available, try an NE to obtain \( \psi \) and \( \Delta \) manually. Automated systems such as an RAE or a PME can take data much faster. For transparent materials, \( \Delta \) is either 0 or \( \pi \), the simple null polarimeter with a PSA system offers satisfactory results [22]. The method is effective near the Brewster angle region. At the Brewster angle \( \theta_p \), \( \psi = 0 \), then \( n = \tan \theta_p \) according to Equation 60.44. For metals whose \( \psi \) is large when \( \Delta = -90^\circ \), the principal angle ellipsometry (PAE) can be used [2]. At the principal angle \( \theta_p \), \( \cos \Delta = 0 \), Equation 60.44 can be simplified to

\[
(n + ik)^2 = \sin^2 \theta_p [1 + \tan^2 \theta_p (\cos 4\psi + i \sin 4\psi)] \tag{60.45}
\]

In PAE, the principal angle \( \theta_p \) is searched and then \( \psi \) is measured. The Stokes polarimeter with a PSA system is suitable to search \( \theta_p \) and measure \( \psi \) for PAE.

Determination of optical constants using reflection ellipsometry is subject to errors caused by surface roughness, natural oxides and surface contamination [15, 16, 41–48]. These effects can be corrected by assuming that there is an effective layer on the surface and then using a least-square regression method to fit the ellipsometric data to the appropriate model [16, 43–48]. Ellipsometry is also used to measure refractive index and thickness of a thin film on a bulk substrate whose optical constants are known [4,
other applications of polarimetry and ellipsometry can be found in recent proceedings about polarization [51–53].

61.1 Introduction

Light is electromagnetic radiation of wavelength about 450 to 700 nm, in which region the human eye is sensitive and refractive index measurements are commonly made. The refractive index or indices of a substance describe an important part of its interaction with electromagnetic radiation. Refractive index is a dimensionless quantity, real for transparent materials and complex if there is absorption. It generally depends on the direction of light relative to axes of the material; such substances, e.g. many crystals, are anisotropic and possess more than one refractive index. In general, the index is a tensor (3 × 3 matrix) with up to 9 components. Many substances are isotropic, e.g., liquids, glasses, and other noncrystalline materials, and one refractive index is sufficient. Some substances are optically inhomogeneous and possess refractive index fluctuations over distances comparable in size with a wavelength. They scatter light and appear milky or turbid. Many foodstuffs and drinks are optically heterogeneous. Refractometry is, fortunately, a robust technique in the face of material complexities. It has widespread application to many industries and materials. This chapter treats the refractive index as the principal measurand; the complications of real materials may require extra attention. Excluded are strongly absorbing materials such as metals in which absorption may be more important than refraction. The appropriate measurement technique is then ellipsometry, in which the amplitude and phase of the reflected light are measured, as the polarization and the angle of incidence are varied. Some refractometric methods are essentially ellipsometric, but for transparent samples transmission methods are also important. Refractive index measurements of high precision, e.g. 10^{-4} to 10^{-5}, are possible with relatively simple techniques. Although ocular instruments remain popular, semiconductor technology has been applied to refractive index measurement in recent years, improving the measurement speed and precision. One of the limits to improvement in precision is the sample's absorption or heterogeneity, a factor considered herein. Several online instruments exist, and the application of refractive index measurements to complex industrial fluids has been recently described [1]. Fiber-optical methods do not yet possess the precision of conventional methods but offer the possibility of remote sensing.
Refractive index is measured for many reasons. It is clearly important to know the refractive index of materials used for their clarity, such as glasses and solid plastics. In complex fluids such as drinks or foods, the refractive index is a measure of dissolved or submicronic material. The Brix scale relates refractive index to sugar concentration. Common industrial applications are to microemulsions to measure their oil/water ratio, to antifreeze to check the glycol/water ratio, and to inaccessible liquids such as the electrolyte of rechargeable cells [2]. The clinical applications of light have stimulated interest in biotissue refractometry [3], and refractometry is useful for the analysis of small samples of biofluids.

### 61.2 Physical Principles

The electromagnetic nature of light and the atomic origin of refraction are described herein only in enough detail to be useful to refractometry; detailed descriptions of them are readily found in optics textbooks [4].

Monochromatic light can be described as an electromagnetic radiation of frequency \( v \) (Hz) and free-space wavelength \( \lambda_0 \). In free space (vacuum), the phase velocity \( c_0 \) is given by \( c_0 = v \lambda_0 \). In a medium or material substance, the phase velocity changes to \( c = v \lambda \), the refractive index \( n \) of that substance then being defined as \( n = c_0/c \). As the frequency is unchanged by entering the medium, \( n = \lambda_0/\lambda \).

In an electromagnetic wave, the vibration directions of the electric and the magnetic fields are 90° apart, and both fields vibrate at 90° to the wave’s direction of propagation. In transparent and nonmagnetic materials, refractive index is determined primarily by the interaction of the electric field of the wave with the permittivity \( \varepsilon \) of the medium. This quantity is written as \( n^\varepsilon = \varepsilon_r \varepsilon_0 \), where \( \varepsilon_r \) is the relative permittivity of the medium, and \( \varepsilon_0 \) is the permittivity of free space being \( 10^7 \times (4\pi \times 10^7) \) F m \(^{-1} \), or about 8.854 pF m \(^{-1} \).

In the wave theory of light, \( n \) is determined by the strength of elastic interaction between the wave’s electric field and the bound charges (electrons and protons) in the atoms and molecules of the medium. For nonmagnetic transparent materials, \( n^\varepsilon \) can be shown if both quantities are measured at the same frequency, and this relation is also closely true if the absorption is weak. Absorption can be ascribed to the inelasticity of the interaction of the wave’s electric field with the bound charges, some of the wave’s energy being turned to heat during propagation.

The time \( t \) and distance dependence of the electric field \( E \) of a wave propagating in the \( z \) direction can be written

\[
E = E_0 \exp\left(\omega t - k_0 z\right) \tag{61.1}
\]

where \( \omega = 2\pi v \) = the pulsation or angular frequency, \( k_0 = 2\pi/\lambda_0 \) = the free-space wave number, and \( i = \sqrt{-1} \). The field \( E \) in Equation 61.1 is complex, and the physical field is understood to be the real part of the complex one, i.e., \( E = E_0 \cos(\omega t - k_0 z) \). The wave amplitude \( E_0 \) is the maximum excursion of \( E \), both quantities being coparallel and normal to the direction of propagation \( z \). The optical power per unit area (radiance) conveyed by the wave is proportional to |\( E \)|\(^2\), or also |\( E_0 \)|\(^2\). The phase velocity \( c \) is given by \( \omega/k \), which the above relations show to be \( c_0/n \). Waves in absorbing media are attenuated as \( z \) increases. This is described by a complex refractive index in Equation 61.1, i.e., writing \( n = n' - n'' \) so that the field oscillates in space and time as before, but decays exponentially with propagation distance \( z \) as \( e^{-k_0 n'' z} \). The cause of the index \( n'' \) may be absorption, scattering, or both.

It will be clear from context whether \( n \) refers to the real part of the complex quantity, or to the complex quantity itself. For the most part, this chapter deals with transparent or only slightly absorbing materials, where \( n'' \) is very small.

Equation 61.1 shows that \( n \) determines the phase of a wave, and this is the basis of the interferometric methods of refractometry, most used for either highly precise measurements on liquids or solids, or for gases where the refractive index is close to 1. Other common refractometric methods rely on the reflection or transmission of light at the interface between the sample and a material of known refractive index. Reflection and refraction of light at optically smooth interfaces are treated (Fresnel relations) in optics textbooks. A description follows that should suffice for the experimental refractometrist.
Simple laws apply to the incident, reflected, and transmitted beams at a planar interface between two transparent media. For brevity, we consider only isotropic media. A parallel-collimated incident light beam produces a parallel-collimated reflected and transmitted beam. All beams are coplanar and define a plane of incidence, which is orthogonal to the planar interface. The interface normal also lies in the plane of incidence. Figure 61.1 shows the incident, reflected, and transmitted beams in the plane of incidence. In the first medium, the angle of incidence and reflection made to the interface normal are equal; both $\theta_1$. The angle of transmission $\theta_2$ into the second medium is given by Snell’s law

$$n_1 \sin \theta_1 = n_2 \sin \theta_2$$  \hspace{1cm} (61.2)

where the subscripts refer to the first and second medium. If $n_1$ is known and the angles are measured, $n_2$ can be obtained.

Equation 61.2 is the basis of deviation refractometry, $\eta$. If $n_1 > n_2$, Equation 61.2 shows that real angles of transmission do not exist for $\theta_1 > \arcsin(n_2/n_1)$; i.e., $\theta_2$ is imaginary. The incident and reflected beams are then of equal power, transmitted light is absent, and the reflection is said to be total. However, although in the second medium no wave propagates, there is an evanescent wave close to the interface, which is nonpropagating and therefore transmits no power. The critical angle is given by

$$\theta_c = \arcsin\left(\frac{n_1}{n_2}\right)$$  \hspace{1cm} (61.3)

(See Figure 61.2.) Reversing the light direction, Figure 61.3 shows that a beam traveling parallel to the interface in the least refractive index medium enters the second medium at a transmission angle also given by $\theta_c$. A full analysis (Fresnel’s equations) shows that, in the region of the critical angle, the reflected or transmitted optical power changes very rapidly with angle of incidence. If there is no absorption, there is actually a discontinuity of reflected or transmitted radiance at $\theta_c$. This makes $\theta_c$ easy to measure accurately and gives the critical angle or Abbe method of refractometry used by most commercial refractometers.
The Fresnel laws of reflection at a plane interface between two media show that if the incident light is linearly polarized with its electric field in the plane of incidence, then there is no reflected light at the Brewster angle \( \theta_B \) given by

\[
\theta_B = \arctan \left( \frac{n_2}{n_1} \right)
\]

(See Figure 61.4.) Measurements of \( \theta_B \), usually in air \((n_i \text{ close to } 1)\), will give \( n_2 \). The reflected optical power is zero at \( \theta_B \) and it increases approximately quadratically for angles below and above \( \theta_B \). Consequently, the Brewster angle method is regarded to be of lower precision than the critical angle method, and so is relatively less used. However, unlike the critical angle method, it does not require a reference medium of higher refractive index than the sample.

If the sample is a finely divided particulate solid or has an irregular interface, none of the preceding methods is useful. Fresnel’s equations show the reflectance of any shape of interface to be zero if the refractive index difference across the interface is also zero. In the method of refractive index match, the turbidity or scattering from a cloud of particles suspended in a liquid is measured, and the refractive index of the liquid is found, which gives minimum turbidity or scattering. The liquid should not swell or interact with the interior of the solid.

### 61.3 Techniques

#### Interferometry

The sample, with parallel input and output faces, is put in the sample beam of a two-beam interferometer (e.g., Rayleigh, Michelson, or Jamin). From Equation 61.1, a sample of length \( z \) and refractive index \( n \) causes a phase lag of \( 2\pi n z/\lambda_0 \), compared with \( 2\pi n_{air} z/\lambda_0 \) for the reference beam in air. The phase difference between the two beams is thus

\[
\delta = \frac{2\pi z(n - n_{air})}{\lambda_0}
\]

The refractive index of air is 1 for approximate purposes, or is known more precisely [5]. Sample insertion causes a step increment of \( \delta \) in the phase difference, which is measured by adjusting a calibrated phase compensator in the reference beam to regain the zero-order fringe of white-light fringes. Equation 61.5 enables \( n \) to be calculated. For gaseous samples, use of the compensator may be avoided by allowing the gas to enter an initially evacuated tube with rigid and parallel window faces placed in the sample beam. As the gas enters slowly, the interference fringes passing a fiducial mark may be counted. Each whole fringe corresponds to a change in \( \delta \) of \( \pi \) radian. The refractive index of a gas depends, through its density, on pressure and temperature. The number of fringes between a vacuum \((n = 1)\) and the gas at a given pressure and temperature will then give the gas refractive index.

In interferometry, the effect of optical attenuation (via absorption or scattering) by a sample of complex refractive index decreases the fringe brightness but does not affect the phase. Thus, only the real part the complex refractive index is measured.
About 0.1 of a fringe can be judged by eye; electro-optic methods can measure $10^{-6}$ of a fringe. The method’s potential precision is very high. However, an interferometer is delicate and expensive, and good sample quality (homogeneity, face parallelism) is necessary. A difference in dispersion (wavelength dependence) of the sample and compensator refractive index can be a problem. For a sufficiently large number of fringes, the dispersion difference between the sample and compensator can make the white-light fringe pattern and zero-order fringe invisible [6]. One solution is to use a compensator more closely matched to the sample dispersion. A cheaper option is to reduce the sample length, with some loss of precision. A major use of the interference method is for gases, where $n - 1$ is about 1000 times less than $n - 1$ of solids and liquids. It is also used in solution differential refractometry, e.g. to measure the concentration in the eluted solvent relative to the pure solvent. A stable folded Jamin interferometer for refractive index measurements is described by Moosmüller and Arnot [7]. Liquid refractive index measurements using a Michelson interferometer are described by Richerzhagen [8].

### Deviation Methods

Lateral and angular deviation methods make use of Snell’s law (Equation 61.2). The incident beam is usually in air, of refractive index $n_{\text{air}}$.

Lateral deviation occurs for a beam of light transmitted through a parallel-sided sample of thickness $L$ (see Figure 61.5). If the incident angle is $\theta_{\text{air}}$, Snell’s law (Equation 61.2) gives

$$
\frac{n}{n_{\text{air}}} = \left[1 + \left(\frac{\cos \theta_{\text{air}}}{\sin \theta_{\text{air}} - \frac{L}{L}}\right)^2\right]^{1/2} \sin \theta_{\text{air}} \quad (61.6)
$$

If $\theta_{\text{air}}$ and $L$ can be measured the most accurately, the precision of the method depends on the accuracy of measuring $l$. Modern electro-optic beam-displacement detection devices permit a precision of a few micrometers in $l$, giving a typical precision in $n$ of about 0.001. The lateral deviation method is suitable for samples in sufficiently thick sheet form.

In the angular deviation method, parallel-collimated light is incident on one face of the sample of refractive index $n$ in triangular prism form with vertex angle $A$, the vertex line of the prism being normal to the plane of incidence (see Figure 61.6). The exit beam deviates angularly from the direction of the incident beam. At the angle of minimum deviation $D$, the analysis is simplest Equation 61.1, showing that

$$
\frac{n}{n_{\text{air}}} = \frac{\sin \left(\frac{A + D}{2}\right)}{\sin \left(\frac{A}{2}\right)} \quad (61.7)
$$

For $A = 60^\circ$, a 1 minute (1’) uncertainty in $D$ gives 0.0003 for the corresponding precision in $n$. Angular deviation requires the sample to be a less convenient shape than the parallel-sided sheet of the lateral deviation method. However, measurements of $D$ and $A$ can be made simply using an ocular goniometer. Lateral or angular deviation methods can be applied to liquid samples in a suitable cell with walls having parallel sides. Such cell walls will, however, give some lateral deviation but not cause angular deviation if used to make a hollow prism to contain a liquid sample. In the Hilger-Chance angular deviation

---

© 1999 by CRC Press LLC
refractometer [9], the liquid sample is contained in a glass 90° V-block of refractive index \( n_{\text{glass}} \), with parallel outer faces. A parallel-collimated light beam incident normally on one outer face of the block suffers angular deviation \( D \) (not minimum), Equation 61.2, giving

\[
D = n^2 \sin^2 D - (n_{\text{glass}}^2 - \sin^2 D)^{\frac{1}{2}} \sin D
\]  

(61.8)

For a 1° uncertainty in \( D \), the precision in \( n \) is about \( 10^{-5} \). Solid samples can be measured by coupling a prism of the sample into the V-block using a thin film of liquid of refractive index intermediate between that of the sample and the prism.

**Critical Angle Method**

In the region of the critical angle, Fresnel's equations show that the transmitted or reflected optical power varies discontinuously with angle. Thus, \( \theta_c \) is accurately measurable and a refractive index precision of about \( 10^{-4} \) to \( 10^{-5} \) is obtained. Liquid samples are placed directly onto one face of the refractometer prism of known refractive index. Solid samples need only one face to be flat and optically polished, which is coupled to face of the refractometer prism using a liquid film of intermediate refractive index. For a transparent sample, either the transmission or the reflection mode can be used, as \( \theta_c \) is the same for both (see Figures 61.2 and 61.3). In the transmission mode, the sample–prism interface is illuminated diffusely through the sample, the critical angle then being the largest angle of transmission in the prism.

In the reflection mode, useful for highly scattering or absorbing samples, the prism–sample interface is illuminated diffusely from within the prism. The critical angle is then where the reflectance changes discontinuously with angle of reflection within the prism, being total for \( \theta \geq \theta_c \). In the transmission mode, the transmittance from the sample into the prism is zero for \( \theta \geq \theta_c \) and finite for \( \theta \leq \theta_c \), whereas, in the reflection mode, typically a few percent of the light is reflected for \( \theta \leq \theta_c \), and 100% is reflected for \( \theta \geq \theta_c \). If the interface is illuminated with diffuse light, the transmission mode gives a dark–bright contrast at the critical angle, with a dim–bright contrast for the reflection mode. For ocular observation, this difference can make the transmission method preferable. Automatic instruments invariably use the reflection mode, this being necessary for samples that attenuate by absorption or scattering. For such samples, however, the discontinuity of reflectance is replaced by a continuous function with a maximum gradient at an angle \( \theta_{\text{max}} \) that differs increasingly from \( \theta_c \) as the sample becomes more absorbing [10–12]. A separate measurement of the absorption index is required before \( \theta_c \) can be obtained from \( \theta_{\text{max}} \). Attempts to improve the precision of critical angle refractometry of nontransparent samples are expected to become increasingly limited by this effect.
The critical angle method, however, is robust and simple to use. Despite the problems associated with optically attenuating samples, it is likely to persist as the preferred method in commercial refractometers.

**Brewster Angle Method**

Here, the angle of reflection $\theta_B$ is measured for which there is no linearly polarized light reflected from the sample surface. Equation 61.4 then gives the sample refractive index, where $n_i$ is the refractive index of the medium containing the incident and reflected light, usually air. The light is polarized such that its electric field vector vibrates parallel to the plane of incidence (see Figure 61.4). A linearly polarized laser is a suitable source of monochromatic light. Nonpolarized sources require polarizing with a Glan-Thomson prism or a quality dichroic polarizer. With a 1 mW HeNe laser and ocular judgement of the minimum reflectance, a precision in $\theta_B$ of about 0.1° can be obtained, giving a precision in the sample refractive index of about 0.005. Precision improvement by factors of 10 to 100 can be expected if photometric analysis replaces the eye. The Brewster angle method is then comparable in precision to the critical angle method. Unlike the critical angle method, however, it does not require a reference material of higher refractive index than the sample. If the sample is absorbing, the reflectance zero at $\theta_B$ is replaced by a reflectance minimum at an angle $\theta_{\text{min}}$. It can be shown that a given absorption produces less error in the Brewster angle method than in the critical angle method [6, 12]. Despite these good features of the Brewster angle method, a commercial Brewster angle refractometer is not known to this author.

**Index Match Method**

The refractive index match method does not require the sample to be in any special shape or form. Thus, it might be finely divided, i.e., a powder. Assuming the particles to be isotropic and homogeneous, then the reflected radiance, the angular or lateral deviation, and the relative phase shift of transmitted light all become zero at refractive index match. If the sample is absorbing, the refractive index of the surrounding liquid which gives the minimum visibility still gives closely the real part of the sample's refractive index. Similarly, if the sample is heterogeneous or anisotropic, the method gives the average refractive index of the sample. The liquid should not dissolve, permeate, or react in any way with the solid sample.

For macroscopic samples a precision of about 0.005 in $n$ has been estimated [6] from the index-match method, where a simple ocular estimation of match is employed. For a matching liquid of refractive index $n_{\text{liq}}$, the reflectance from an interface varies approximately as $(n - n_{\text{liq}})^2$. This quadratic dependence makes the sensitivity of the method decrease as the match is approached, and makes it difficult in practice to judge whether $n_{\text{liq}}$ should be increased or decreased to improve the match.

**Microscopy and Scattering Methods**

The refractive index of individual particles large enough to image in a microscope can also be measured by the index-match method. Central or oblique illumination modes can be used corresponding to the Becke, and Schroeder-Van der Kolk methods, respectively, which utilize null deviation at refractive index match. A precision of 0.0002 in $n$ is quoted [13] for the Becke line method. Whether $n_{\text{liq}}$ is lesser or greater than the sample’s refractive index $n$ is shown by the appearance of the image.

The phase difference between light transmitted through and around the particle is proportional to $n - n_{\text{liq}}$, so that the phase changes sign each side of match. This is used in measurement of refractive index of particles by phase-contrast or interference microscopy, in which the image is brighter or darker than the background according to whether $n > n_{\text{liq}}$ or $n < n_{\text{liq}}$. These methods can measure the refractive index of particles below the conventional resolving limit, as the details of an object need not be fully resolved in order to discern match or otherwise. Users of microscopy in refractometry should refer to texts on phase-contrast and interference microscopy. Newer forms of optical microscopy (e.g., scanning confocal) have greater resolving power and can be used for refractive index matching of finer particles.

For a suspension of particles smaller than about 1 µm, the optical turbidity and light scattering are zero at refractive index match, leading to turbidimetric or nephelometric methods of measuring the
particle refractive index. For particles of colloidal size, it is important to avoid aggregation or flocculation, and suspension destabilization. Thus, chemical restrictions can preclude the attainment of match, particularly if the particle’s refractive index is large compared with $n_{\text{liq}}$. In such cases, the turbidity $E$ is measured for changes in $n_{\text{liq}}$ which do not destabilize the suspension, and the value of $n_{\text{liq}}$ is found by extrapolation to $E = 0$. Extrapolation to obtain this value of $n_{\text{liq}}$ is difficult unless the experimental parameters can be arranged to have a linear relation. Theory and experiments described by Griffin and Griffin [14] showed that linearity is obtained if $n_{\text{liq}}/E$ is plotted versus $n_{\text{liq}}$.

**Anisotropic and Heterogeneous Materials**

If a plane face is made from a general optically anisotropic sample, and this face is then offered to the prism of a critical angle refractometer, two critical angles can be simultaneously observed. One can be enhanced over the other through the use of a linear polarizer rotated in the incident or refracted light path. The interpretation of these critical angles, in the general case, is not simple, and the reader is referred to analyses [15–17]. Similar complexity is visited upon the Brewster angle method if the sample is anisotropic, and again the reader is referred to Reference 6 for works on ellipsometry.

Highly turbid samples, such as polymer latexes and other concentrated colloidal fluids, have been investigated using the critical angle method [1, 18–20]. It appears that if the particle size is less than about half a wavelength, the critical angle method remains successful for volume fractions up to at least 0.5. For high concentrations of larger particles, there is a rapid degradation of the reflectance or transmittance discontinuity at the critical angle. This angle is replaced by a region where the reflectance or transmittance may vary in an unexpected way as the particle size and concentration increase.

The effect of heterogeneity on the reflection of polarized light, and on the Brewster angle, is also affected by sample heterogeneity [21, 22]. Whereas for a homogeneous sample the parallel-polarized reflectance at the Brewster angle is zero, the effect of sample heterogeneity on the wavelength scale is to cause finite reflectance. Comparison of the Brewster angle and the critical angle methods for heterogeneous materials awaits investigation.

Gate and coworkers have measured the refractive index of emulsion paint films [23] and coated paper [24] by a non-Brewster angle reflection method. Both materials were strongly heterogeneous on the wavelength scale and so (in air) had a strong nonspecular or diffuse reflectance. Some specular reflection remained, however, and the method derived the refractive index of the surface of the film from the ratio of the specular reflectances at a non-Brewster angle for polarizations parallel and normal to the plane of incidence.

The application of refractometry to heterogeneous and absorbing samples is clearly a developing art and, although it is clear that refractometry offers valuable information, the refractometrist should use existing instruments critically.

### 61.4 Review of Refractometers

The author’s initial review of refractometer manufacturers revealed about 30 companies, and the true number may be more than 50. A very large number of general- and special-purpose instruments are offered by each company, e.g., 31 different models by the Atago Co., Ltd. It is clearly not possible to review, compare, and advise on individual models. The aspiring refractometrist should do this according to needs and budget. The generalities that follow should assist.

Most instruments use the critical angle (or Abbe) method. They thus have a prism of known refractive index with a face to which the sample is offered. The larger manufacturers offer three types of critical angle instrument:

1. The portable hand-held models, which require no power or battery and are customized and calibrated for Brix (sugar), urine, antifreeze, cutting oil, etc. Their refractive index precision is typically between $10^{-3}$ and $10^{-4}$, but their range is small owing to their particular application. The user looks into an eyepiece and reads a scale on which is superposed the dark–light boundary
caused by transmission or reflection in the region of angle each side of the critical angle; often
termed the critical edge. The price varies greatly between models and manufacturers, typically
U.S. $200 to $400.

Some manufacturers offer a digital readout portable models, of similar weight (less than 1 kg)
and precision, and battery powered. These cost roughly U.S. $1000 to $2000.

2. The laboratory (Abbe) refractometer, which has a refractive index precision of typically 10⁻⁴ to
10⁻⁵ and covers a wide range of refractive index, typically 1.3 to 1.75 in a low refractive index
instrument, and 1.4 to 1.85 in a high refractive index model. Such instruments are calibrated so
that the temperature can be varied using an external liquid bath, and the wavelength can be varied
using external light sources. Very roughly, their weight, cost, and precision are about 10 times that
of the portable instruments in (1) above. They require the user to estimate the position of the
critical edge on a graduated scale viewed through an eyepiece.

3. The digital refractometer. Compared with those in (2) above, these have similar precision and
general facilities, a cost typically a few times greater, but with the advantage of a digital or electronic
readout of the data. The upper refractive index offered by several manufacturers appears to be
restricted to about 1.55.

4. The process refractometer is a version of those described in (3) above, but where the prism is
mounted to contact a fluid in a reactor or a pipe, and viewed via a fiber-optic cable. Thus, high
pressures and temperatures can be accommodated. The prism is usually of sapphire to avoid wear
of the optical face, and the precision generally tend to be somewhat lower than those described
in (2) and (3) above.

62.1 Introduction

For nearly 50 years, turbidity measurements have been used to perform a wide variety of physical measurements. These include the determination of particle concentration per unit volume when the scattering cross-section per particle is known, the determination of particle size (scattering cross section) when the concentration of particles is known [1–3], and the determination of some of the critical exponents associated with second-order and nearly second order phase transitions [4–7].

The basic ideas necessary to understand turbidity measurements are fairly simple. In the absence of reflection losses, when a weak beam of light passes through a dielectric sample, the two processes most responsible for reducing the intensity of the transmitted beam are absorption and scattering. The reduction in transmitted light intensity due to scattering is called the sample’s turbidity. Extinction includes the effects of both absorption and scattering. The Beer-Lambert or Lambert law describes the effects of both absorption and turbidity on the transmitted intensity. This law is written as:

\[ I_T = I_0 \exp(-\alpha l) + \exp(-\tau l) \]

where \( I_T \) = intensity of the light transmitted through the sample, \( I_0 \) = intensity of the light incident on the sample, \( \alpha \) = absorption coefficient per unit length, \( \tau \) = turbidity per unit length, and \( l \) = length of the light path in the sample. As discussed below, it is more correct to use powers rather than intensities, thus this equation should be written as:

\[ P_T = P_0 \exp(-(\alpha + \tau) l) \]  

(62.2)

The most general situation is to have an absorbing medium with absorbing and scattering particles embedded within it; however, the focus here is on the simpler case of nonabsorbing medium and consider the two most common cases: nonabsorbing particles in medium and scattering caused by fluctuations in the medium itself.
Instruments generally fall into two categories: commercial and laboratory constructed. The commercial units are of two general types: (a) attachments to spectrophotometers, and (b) white-light turbidity meters, which operate under ambient conditions. Anyone interested in the former should consult the catalog of accessories for the instrument in question. Those interested in the latter should check under “nephelometers” in scientific supply catalogs. Units of this type perform their designed function admirably and probably are sufficient for routine work. However, they may need modification for the more specialized measurements performed in many research laboratories. For this reason, it is common to construct special laboratory instruments. These come in at least two types, most commonly either single-beam or dual-beam instruments. The single-beam instrument usually has an intensity-stabilized light source, whereas the dual-beam instrument corrects for drift in the light source and reflection losses by either electronically or mathematically taking the ratio of the transmitted light power and a reference beam power.

The balance of this chapter is divided into three parts. The first part briefly discusses the physical basis of turbidity measurements and demonstrates how such measurements may be used to infer the scattering cross section of the particles in the solution or the concentration of the scatterers in the solution. The second section discusses turbidity of pure fluids and shows how certain critical exponents may be determined from such measurements. The last section discusses laboratory instruments and the relative trade-offs involved in such instruments.

62.2 Extinction and Turbidity: Particles in a Nonabsorbing Medium

Suppose that electromagnetic radiation is incident upon a slab of medium consisting of randomly positioned particles and that the transmitted radiation is detected as shown in Figure 62.1. For the present discussion, assume that the source and detector are in the medium. The radiation that is received by the detector will be less than that incident on the slab because of the presence of the particles in the medium—the particles have caused extinction (or attenuation) of the beam. The extinction of the radiation depends on two physical processes, scattering and absorption, whereas the turbidity depends only on scattering. In scattering, there is no change in the total energy of the radiation; rather, some of

![FIGURE 62.1 Idealized experiment indicating the physical basis of turbidity.](image)
the incident radiation is redistributed away from the incident direction. In absorption, some of the energy of the incident beam is transformed into other energy forms. This extinction of the beam is rather complicated; it will, in general, depend on the chemical composition, size, shape, number, and orientation of the particles; the chemical composition of the medium; and the frequency and polarization of the incident radiation [2,3].

In discussions of scattering one often focuses on the cross sections, \( C_i \), of the particles. On the basis of conservation of energy one must write:

\[
C_{\text{ext}} = C_{\text{scatt}} + C_{\text{abs}} \tag{62.3}
\]

where \( C_{\text{ext}} \), \( C_{\text{scatt}} \), and \( C_{\text{abs}} \) = cross sections for extinction, scattering, and absorption, respectively. These cross sections all have the dimension of area, and in all cases a larger cross section (area) indicates a larger effect, and a smaller cross section a smaller effect. In general the cross section will depend on all the intensive quantities that describe the extinction. Finally, note that for nonabsorbing media, \( C_{\text{abs}} = 0 \).

To see how this relates to the measured turbidity, assume now that the medium is nonabsorbing, that all the particles are nonabsorbing and have the same scattering cross section (\( C \)), and that there are \( n \) of these particles per unit volume. Then, one obtains the following expression for the transmitted light power:

\[
P_T = P_0 \exp\left(-nC\right) \tag{62.4}
\]

where \( P_T \) = transmitted power, and \( P_0 \) = incident power. We have switched from intensity to power because power is the quantity detected, and power is independent of the details of the spatial distribution of electromagnetic radiation. Upon noting this change and comparing this to Eq. 62.2, when \( \alpha = 0 \), it is clear that the turbidity can be expressed as

\[
\tau = nC \tag{62.5}
\]

Thus, a measured turbidity can be related to \( C_{\text{scatt}} \) if \( n \) is known, or \( n \) may be determined if \( C_{\text{scatt}} \) is known. The difficulty is then in determining \( C_{\text{scatt}} \). There are a number of approaches that can be used. For well characterized particles, theoretical expressions may be determined [2]. In the absence of such theory, measurements may be made as a function of concentration and then, since \( \tau = nC \), \( C \) may be determined. The generalizations to account for nonmonochromatic beams and extinction by a collection of noninteracting particles of the same type but different sizes are straightforward. The simplest generalization to include different sizes assumes that there is one parameter, \( \zeta \), that describes the distribution of particle size and the corresponding \( C_{\text{scatt}} \) [1]. That is, let \( C_{\text{scatt}}(\zeta) \) be the scattering cross section for a particle characterized by the parameter (for instance, radius) \( \zeta \) and let the number per unit volume with parameter between \( \zeta \) and \( \zeta + d\zeta \) be \( N(\zeta)d\zeta \), such that

\[
n = \int_0^\infty N(\zeta)d\zeta \]

Then

\[
\tau = \int_0^\infty C_{\text{scatt}}(\zeta)N(\zeta)d\zeta \tag{62.6}
\]

A similar integral exists when the incident radiation is not monochromatic, but, in this case, the average is over the wavelength variation of the incident radiation.
62.3 Turbidity Due to Density Fluctuations in Pure Fluids

It is well known that even in very pure and well filtered liquids, in which there are essentially no particles, there is still some reduction in the detected power due to scattering [3]. The explanation is that there are always thermal fluctuations in the dielectric constant of the media, $\varepsilon$, and it is these fluctuations from the mean dielectric constant that lead to the scattering of light. Through application of thermodynamic and statistical mechanical principles [3], the following expression for the turbidity results:

$$\tau = \frac{8\pi^3}{2\lambda^4} \left[ \rho \left( \frac{\partial \varepsilon}{\partial \rho} \right)_T \right]^2 kT \beta_T$$  \hspace{1cm} (62.7)

where $\rho =$ density, $\varepsilon =$ dielectric constant, $k =$ Boltzmann’s constant, $T =$ absolute temperature, $\lambda =$ wavelength of the incident light, and $\beta_T =$ isothermal compressibility. Near a second order phase transition the fluctuations become correlated over larger distances, and this expression must be generalized to include the effects of this increase in the correlation length, $\xi$. In this case the turbidity is given by [5]

$$\tau = A \pi \beta_T \left[ \frac{2\alpha^2 + 2\alpha + 1}{\alpha^3} \ln(1 + 2\alpha) - \frac{2(1 + \alpha)}{\alpha^2} \right]$$  \hspace{1cm} (62.8)

where

$$A = \frac{\pi^2}{\lambda^4} \left[ \rho \left( \frac{\partial \varepsilon}{\partial \rho} \right)_T \right]^2 kT \quad \text{and} \quad \alpha = 2 \left( \frac{2\pi n \lambda}{\lambda} \xi \right)^2$$

where $n$ is the (mean) index of refraction of the fluid. Both the isothermal compressibility and the correlation length exhibit approximate power-law behavior of the form

$$\beta_T, \xi \sim \left( \frac{T_c - T}{T_c} \right)^{x_i}$$  \hspace{1cm} (62.9)

near these phase transitions. Thus, a measurement of $\tau(T)$ allows the determination of the critical exponents, $x_i$, and the values of $\beta_T$ and $\xi$ far from the phase transition. This technique has been generalized to binary liquid mixtures, liquid crystals, and other systems. In these cases, the isothermal compressibility is replaced by the appropriate generalized susceptibility. There are also, in some cases, small corrections to the above expressions. These can also be found in References 8–10.

62.4 Design of Laboratory Instruments

When more exact measurements are required than can be obtained using commercial instruments, and other enhancements such as mK temperature and/or pressure controlled sample chamber are required, it is common to construct a turbidity instrument. There are basically two types of instruments (single-beam and dual-beam). With both types of instruments, both ac and dc detection schemes are possible. Generally, the long-term time stability of synchronous ac detection techniques is superior to dc techniques. This section discusses all of these techniques.

Single-Beam Instruments: Optics

The basic optical design of a single-beam instrument is shown in Figure 62.2. The light source is a low power (1 to 5 mW) vertically polarized He-Ne laser. It is important to use a polarized laser. The
polarization direction of an unpolarized laser wanders, and this can lead to time-dependent reflection coefficients from the various surfaces in this instrument, and hence reduced performance. The beam passes through a laser intensity stabilizer. This device reduces long-term drift in the laser power to \(\leq 0.1\) percent, thus allowing single-beam operation. Table 62.1 shows several commercial intensity stabilizers.

To reduce any possible heating of the sample due to absorption, the beam is then passed through a neutral density filter, which attenuates the beam further to a level of 50 to 100 \(\mu\)W. The next item in the beam line depends on the detection scheme. For ac operation a light chopper is inserted into the beam line, while for dc detection nothing else is required before the sample. An output from the chopper is used for synchronous detection. The sample chamber then follows. This chamber requires an input and an output port and a design that precludes interference of any beam with other reflected beams. Other design details are determined by the materials to be studied and any required external factors that are to be controlled. After the beam has been transmitted through the sample, it passes through either a pinhole or a lens-pinhole combination [11, 12]. This results in a small angle of acceptance for the detector which, in turn, reduces the scattered light at small angles from the transmitted beam that reaches the detector. A detector then completes the optical train. For most applications, a pin photodiode is an excellent, inexpensive detector; however, in some applications, other types of detectors may be superior.

**Single-Beam Systems: Electronics**

For both synchronous and dc detection, the output of the photodiode, which is a current device, must be transformed into a voltage using a current-to-voltage converter (CVC). It is important not to use just a resistor for this function. The simplest workable current-to-voltage converter uses an FET-input operation amplifier such as an LM-11 and one resistor. The circuit, also known as a transimpedance amplifier, is standard and can be found in many sources [13].

When dc detection is used, the output voltage from the CVC is read on a voltmeter. The relationship between this voltage and the turbidity will be discussed below. The stability of dc operation is greatly improved by maintaining the photodiode and the electronics at a stable temperature. The drifts in detector
efficiency and in component values associated with temperature changes can limit the accuracy of the instrument. Furthermore, the detector must be shielded from stray light, which means the instrument must be operated in a darkened room or under a light tight cover. Such covers may cause excessive heating of the laser and the system. A “spike” filter that passes the wavelength of the laser may also assist in solving this problem.

When synchronous ac detection is used, the output from the CVC is the input to a lock-in amplifier which is synchronized to the chopper. Commercial units are available and can be used. One can also construct a simple lock-in using an Analog Devices AD-630 balanced modulator/demodulator, a phase shifter to ensure that the reference signal and the transmitted signal are in phase, and an RC filter. The output voltage from the RC filter is then read with a dc voltmeter. The necessary wiring diagrams are available from Analog Devices [14]. Synchronous detection has the advantage of having lower 1/f noise than dc circuits. Also, synchronous detection can discriminate against signals not synchronized with the reference, and hence offers much greater immunity to room lights and other stray light sources. The advantages of such detection are discussed elsewhere [13, 15].

Single-beam techniques are most useful for measuring changes in turbidity. To see this, note that the voltage output from the current-to-voltage converter or the lock-in, \( V_t \), is given by \( V_t = A P_T \), where \( A \) is an instrument constant that includes factors such as current-to-voltage gain, light power level to current conversion in the photodiode, reflection losses from the various interfaces, incident light power, gain of the lock-in, and so on. Now, \( P_T \) is given by Equation 62.2, hence \( V_{dc} \), the measured dc voltage may be written as:

\[
V_{dc} = B \exp \left( \alpha - \tau \right) \tag{62.10}
\]

where \( B = AP_o \) is another constant, and we have included absorption. \( B \) may be determined by putting a solution of known extinction in the instrument and solving Equation 62.10 for \( B \). Then, knowing \( I, \alpha, B, \) and \( V_{dc} \), the turbidity may be found by solving Equation 62.10 for \( \tau \), that is

\[
\tau = \frac{1}{I} \ln \left( \frac{V_{dc}}{B} \right) - \alpha \tag{62.11}
\]

This technique is rather limited if a large number of different samples must be compared. For a given sample, the change in turbidity is easily measured as a function of externally controlled parameters. However, putting samples into and taking them out of the instrument usually produces small random errors that slightly change the instrumental constant \( A \) and degrade performance. In some cases, the difference in turbidity between two samples may be small and result in a situation in which one must deal with a small difference of large numbers. This situation may be rectified using dual-beam instruments.

**Dual-Beam Instruments: Optics**

The optical design of a dual-beam, two-detector instrument is shown in Figure 62.3. The first several parts of the optical train are the same as for the single-beam instrument, and the same comments apply in this case. The first real difference is that there need not be an intensity stabilizer in the dual-beam system. However, inclusion of the intensity stabilizer may improve system performance. The second difference is the inclusion of a beam splitter which splits the laser beam into two parts. We have found that a microscope slide works well as a beam splitter [16]. One of these beams (usually the reflected beam) becomes a reference beam that passes through a reference sample. The other passes through the sample as in the single-beam instrument. The beams from these two paths go through lens-pinhole combinations and fall on detectors. All of the comments that apply to the single-beam instrument also apply here. The associated electronics are also identical. Once more, both dc and ac detection may be used. Experience in our laboratory shows that the best results are obtained when the sample signal is
simultaneously divided by the reference signal using an integrated circuit divider. A modification that uses two beams and one detector is shown in Figure 62.4. This modified design eliminates the need for absolute stability of two separate detectors but requires somewhat more complex optics.

The following analysis assumes that the measured output is the ratio of the sample signal voltage to the reference signal voltage. Let the voltage output from the detector’s CVC be $V_{\text{sig}}$, and the voltage output of the reference signal detector’s CVC be $V_{\text{ref}}$. Then

$$V_{\text{sig}} = AP_T$$  \hspace{1cm} (62.12)

and

$$V_{\text{ref}} = CP_R$$  \hspace{1cm} (62.13)

where $A$ and $C$ = instrumental constants totally analogous to the instrumental constant $A$ above, and $P_R$ = the power of the reference beam at the detector. It is important to realize that $A$ and $C$ are constant, but they need not be identical. The output voltage ratio, $V_{\text{out}}$, is given by:

$$V_{\text{out}} = \frac{V_{\text{sig}}}{V_{\text{ref}}} = \frac{AP_T}{CP_R} = \frac{DP_T}{PR}$$  \hspace{1cm} (62.14)

where $D = A/C$ is a constant. Note that, in this arrangement, common multiplicative noise on the two voltages will tend to cancel out. Now $P_T$ can be replaced by Equation 62.1, and $P_R$ is given as
where \( \alpha_R \) = absorption, \( \tau_R \) = turbidity of the sample in the reference beam, \( l_R \) = thickness of the sample in the reference beam, and \( f \) is a constant determined by the beam splitter. Then, assuming that \( l_R \) is the same as \( l \) the following expression results:

\[
P_R = f^* P_0 \exp(- (\alpha_R + \tau_R) l_R)
\]  

(62.15)

and thus:

\[
V_{\text{out}} = D' \frac{P_0 \exp-(\alpha + \tau) l}{f^* P_0 \exp-(\alpha_R + \tau_R) l}
\]  

(62.16)

where \( D' = D / f \). Often, this can be considerably simplified when the reference sample is a pure liquid because then \( \tau_R \) is of order 10^{-5}, and \( \alpha_R \) is totally negligible. Normally, the reference sample is chosen so that its optical properties approach those of the sample in the case where the concentration of particles is low or the system is far from a phase transition. The constant \( D' \) may be determined by using the same sample in both the reference and the signal arms of the instrument—in this case \( V_{\text{out}} = D' \).

### Dual-Beam Instruments: Electronics

The electronics for dc detection consists of two CVC converters, one for each detector. The voltage outputs from these may be read directly. However, experiments indicate that greater stability is achieved by simultaneously dividing these two signal outputs as discussed above. In our laboratory, this is accomplished using an Analog Devices AD-532 internally trimmed integrated circuit divider. These can be purchased with different accuracies. In the present application, they typically perform slightly better than the factory specifications indicate. The circuit details are available from Analog Devices [17].

The electronics for ac detection generally consist of two synchronous detectors followed by division of the sample signal by the reference signal. Once more, this may be accomplished using two Analog Devices AD-630 balanced modulator/demodulators or two commercial lock-in amplifiers. Division can be accomplished in the same way as in the dc technique section.

### 62.5 Limitations

Highly turbid samples, which transmit very little light, may be difficult to measure using a photodiode. In such cases, the photodiode in the sample arm may be replaced with a photomultiplier (PM). In this case, a chopper can be used to reduce the effects of the dark signal from the PM. The outputs, when the signal is present and when it is blocked, are both measured and averaged (preferably digitally), and the difference is computed. By counting for a fixed number of reference counts (requiring another PM), drift in the source may be eliminated. A Stanford Research Instruments photon counter [18] may be configured in this mode. Furthermore, unless extreme precautions are taken in this situation, erroneous results may occur because the scattered power is as large or larger the transmitted beam power.

63.1 Introduction

A laser is a device that emits an optical beam. A laser beam carries a certain amount of optical power. Lasers emit beams in two different ways: continuous wave (CW) or pulsed. A CW laser emits a steady power as shown in Figure 63.1. CW laser power is measured in terms of watts. The power of commonly used CW lasers ranges from a fraction of milliwatts for a small helium neon (He-Ne) laser to tens of kilowatts for a carbon dioxide (CO$_2$) laser. A pulsed laser emits a pulsed power as shown in Figure 63.2. The pulse can be repeated. The pulse duration and repetition rate vary for lasers of different types and are adjustable for some types of lasers. Pulsed laser power is more easily measured in terms of energy per pulse such as joules per pulse. The term “per pulse” is usually omitted. The energy of commonly used pulsed lasers ranges from a few picojoules for a semiconductor laser to tens of megajoules for a semiconductor laser array. The pulse repetition rate ranges from a single pulse for an excimer laser or

![Figure 63.1](figure.png)
an X-ray laser to hundreds of megahertz for a neodymium:YLF laser. The pulse duration ranges from
tens of femtoseconds for a Ti:Sapphire laser up to continuous wave for a CO₂ or He-Ne laser.

A laser beam may contain more than one wavelength (monochromatic) component. One wavelength
component may have an optical intensity different from that of another wavelength component. Optical
spectral intensity is defined as power per unit wavelength. The optical intensity-wavelength profile of a
laser beam is known as the “spectrum.” Spectrum measurement usually means measuring the spectral
profile. The absolute value of the optical spectral intensity is in fact not important. Figure 63.3 shows a
typical spectrum of a multimode semiconductor laser. The wavelength components are inside several
bands. Each band may be a “longitudinal mode,” and the width of a band is known as the “mode
linewidth.” Figure 63.4 shows a typical spectrum of a single mode He-Ne laser. There is only one
longitudinal mode with a very narrow linewidth. The power of a laser beam can be calculated by
integrating over the laser spectrum.

The wavelength of a laser is referred to as the central wavelength of the spectrum. But the term “central”
is usually omitted. For example, the wavelength is 780 nm for the semiconductor laser shown in Figure
63.3 and is about 632.8 nm for the He-Ne laser shown in Figure 63.4. The wavelength of commonly used
lasers ranges from 270 nm in ultraviolet for a neodymium:YAG laser, or even lower for an X-ray laser,
to 10.6 μm in infrared for a CO₂ laser. Many lasers have a beam with single longitudinal mode and very
narrow linewidth like that shown in Figure 63.4. The spectrum measurement for these lasers then virtually
reduces to wavelength measurement.

Power, spectrum, and wavelength are the three most important parameters describing a laser. Laser
manufacturers should provide information about these three parameters of their lasers. Some lasers have
adjustable power, spectrum, or wavelength. Users often need to measure these parameters to ensure

![Figure 63.2](image1.png)

**FIGURE 63.3** Spectrum of a multimode semiconductor laser.
63.2 Measurement of Laser Power

A laser power meter can measure laser power or energy. Figure 63.5 shows the scheme of a laser power meter. The three basic components of a laser power meter are a photodetector, an electronic conditioner, and a display device. The photodetector detects the laser beam under measurement and outputs an electrical response proportional to the laser power. The electronic conditioner processes the response and provides a digital or analog signal for displaying. The display device displays the measurement result in terms of watts or joules. To a large extent, the characteristics of the photodetector used determines the performance of a laser power meter. When selecting or using a laser power meter, the following issues are of primary concern:

1. **Spectral response range.** A photodetector has a certain spectral response range that limits the spectral range of a laser power meter. Some photodetectors have a wavelength-dependent spectral response. Calibration is necessary when using a laser power meter with such a photodetector to measure the power at different wavelengths.

2. **Power range.** The detection threshold and damage threshold of a photodetector usually determine the power range of a laser power meter. Incident laser power lower than the detection threshold can cause measurement error, while incident power higher than the damage threshold can cause permanent damage to the photodetector. Specifically, power range includes CW power range, peak power range, and pulse power range.
power range, spatial power density range, single-pulse energy range, and spatial energy density range. An optical attenuator put in front of the photodetector can raise the damage threshold to as high as megawatt. However, an attenuator will also raise the detection threshold.

3. **Response time.** A photodetector needs a certain time to respond to an incident laser beam. In order to determine the shape of a laser pulse, the detector response time must be shorter than the width of the pulse.

4. **Detector window size.** The input window size of commonly used photodetectors are from a few to tens of millimeters. When the size of a laser beam under measurement is larger than the detector window size, focusing optics must be used to reduce the beam size. Power loss caused by the focusing optics must be excluded to avoid measurement error.

**Photodetectors**

Three photodetectors are commonly used in laser power meters. They are thermopiles, photodiodes, and pyroelectric probes.

**Thermopiles**

A thermopile is usually a light absorber disk onto which a ring of thermocouples has been deposited. The absorber converts the laser power incident on it into heat and generates between the absorber and a heat sink a temperature difference proportional to the incident laser power. The thermocouples generate and output an electrical response proportional to the temperature difference. Thermopiles usually have a long response time of a few seconds, a broad and flat spectral response range from 200 nm to 20.0 \( \mu m \), and a power range of 1 mW to 5 kW for CW lasers or 0.01 J to 300 J for pulsed lasers. Because of the flat spectral response, calibration is independent of wavelength. Thermopiles are primarily used to measure moderate to high power output of CW lasers, moderate to high energy output of single-shot pulsed lasers, and the energy output of pulsed lasers with a repetition rate higher than 10 Hz.

**Photodiodes**

Silicon and germanium photodiodes are widely used as photodetectors. A photodiode absorbs the photons (laser beam) incident on it and utilizes the photon energy to create free carrier pairs (electrons and holes). These free carriers form a response current in an external circuit. The responsivity of a photodiode in amps/watt is given by

\[
R \left( \frac{A}{W} \right) = \eta_D \frac{e}{h \nu}
\]

where \( R = \) current produced by the photodiode for per watt of incident power, \( \eta_D = \) detection efficiency, \( e = \) electron charge \((1.6 \times 10^{-19} \text{ C})\), and \( h \nu = \) photon energy. Since a typical photon energy is 2 eV \( = 3 \times 10^{-19} \text{ J} \), \( e/h \nu = \) is of the order of 0.5 A/W. Normal detection efficiencies \( \eta_D \) exceed 0.5 at optical wavelengths (500 to 800 nm), leading to typical responsivities of 0.25 A/W. Silicon photodiodes have a narrow spectral response range (400 nm to 1.1 \( \mu m \)). The response peak is at about 800 nm. Germanium photodiodes also have a narrow spectral response range (800 nm to 1.8 \( \mu m \)). The response peak is at about 1.5 \( \mu m \). Photodiodes usually have a power range of 1 nW to 50 mW for CW lasers or 1 pJ to 1 \( \mu J \) for pulsed lasers, and a short response time of about 100 ms. Photodiodes are best for measuring low power output of CW lasers or low energy output of pulsed lasers. Because their spectral response is wavelength dependent, calibration is always required when measuring the power of lasers with different wavelengths. Manufacturers should attach a calibration data sheet to their laser power meters that use a photodiode as the detector. Several other semiconductor photodetectors with different spectral response ranges are available commercially. For example, the spectral response ranges are from 1.0 to 3.6 \( \mu m \), 1.0 to 5.5 \( \mu m \), and 2 to 22 \( \mu m \) for indium arsenide photodetectors, indium antimonide photodetectors, and mercury cadmium telluride photodetectors, respectively.
Pyroelectric Probes

A pyroelectric probe uses a ferroelectric material that is electrically polarized at a certain temperature. The material is placed between two electrodes. Any change in temperature of the material caused by the absorption of laser power produces a response electric current in the external circuit. Pyroelectric probes are primarily used to measure the energy of pulsed lasers because they only respond to the rate of temperature change. Pyroelectric probes usually have a spectral response range from 100 nm to 100 μm, a response time as short as a few picoseconds, and a pulsed energy range from 10 nJ to 20 J.

Integration Spheres

Integration spheres are designed to collect the power of highly divergent laser beams, such as semiconductor laser beams, since these beams can overfill the input window of a photodetector and cause considerable measurement error. Figure 63.6 shows the scheme of an integration sphere. The hollow spherical cavity has a diffusive internal wall and at least two windows. The reflectivity of the internal wall is high and slightly wavelength dependent. The highly divergent laser beam under measurement is incident into the sphere from one window. The photodetector of a laser power meter is mounted on another window. A baffle is used to prevent the photodetector being directly hit by the incident beam. The sphere can collect all the incident laser power and convert the power into a diffusive radiation proportional to the power. The laser power meter measures the radiation and displays the laser power under measurement based on the calibration data of the integration sphere.

Readers interested in knowing more about laser power meters can read References 2 through 4 or contact manufacturers. Section 8.1 of this handbook provides more information about photodetectors.

63.3 Measurement of Laser Spectrum

An instrument that can measure a laser spectrum is known as an optical spectrum analyzer. An optical spectrum analyzer consists of two basic components: an optical device and a laser power meter. The optical device can select and output a certain wavelength band of a polychromatic laser beam incident on the device. The central wavelength of the output wavelength band can be scanned over a certain range by the scan of the optical device. The laser power meter measures the power of the optical device output. The width of the output wavelength band usually does not change. Therefore, the power measured by the power meter is proportional to the optical spectral intensity. Since the absolute value of the optical spectral intensity is not important in the measurement of spectrum, the laser power meter sometimes can be as simple as a photodiode combined with a voltmeter. As the optical device is scanned, the power meter outputs the power (optical spectral intensity) as a function of the wavelength, and thereby measures the spectrum. Diffraction gratings and scanning Fabry-Perot interferometers (SFPI) are two widely used optical devices for spectrum analysis.

![Figure 63.6 Scheme of an integration sphere.](image-url)
Light Interference

Most optical spectrum analyzers make measurements utilizing light interference. The wave theory of light can explain interference. A single mode narrow linewidth laser beam can be described by its electric field \( E(z) \):

\[
E(z) = A \exp[-i \phi(z) + i \alpha(t)]
\]  

(63.2)

where \( A \) = amplitude, \( \phi(z) = 2\pi z/\lambda \) = phase, \( \lambda \) = laser wavelength, \( z \) = coordinate in the direction of beam propagation, and \( \alpha(t) = \) a phase factor that varies fast with time \( t \). The intensity of the laser beam is given by:

\[
I = |E(z)|^2 = A^2
\]  

(63.3)

Two-Beam Interference

A beam splitter such as a partially transparent plate can split a laser beam into two described by:

\[
E_1(z) = A_1 \exp[-i \phi(z) + i \alpha(t)]
\]  

(63.4)

\[
E_2(z) = A_2 \exp[-i \phi(z) + i \alpha(t)]
\]  

(63.5)

where \( A_1 \) and \( A_2 \) are the amplitudes. Let the two beams propagate through two different distances, \( z_1 \) and \( z_2 \), respectively, and then be recombined into one. The intensity of the recombined beam is:

\[
I = |E_1(z_1) + E_2(z_2)|^2 = A_1^2 + A_2^2 + 2A_1A_2 \cos \left( \frac{2\pi(z_2 - z_1)}{\lambda} \right)
\]  

(63.6)

Equation 63.6 shows that \( I \) varies sinusoidally as \( |z_2 - z_1| \) is varied. Such a phenomenon is known as two-beam interference. When \( |z_2 - z_1| = m\lambda \) (\( m \) is any integer), \( I \) takes the maximum value of \( (A_1 + A_2)^2 \) and the situation is called “constructive interference.” When \( |z_2 - z_1| = (m + 1/2)\lambda \), \( I \) takes the minimum value of \( (A_1 - A_2)^2 \), and the situation is called destructive interference. Combining two beams with the same wavelengths but from two different lasers results in:

\[
I = A_1^2 + A_2^2 + 2A_1A_2 \cos \left( \frac{2\pi(z_2 - z_1)}{\lambda} \right) + \alpha_2(t) - \alpha_1(t)
\]  

(63.7)

where \( \alpha_1(t) \) and \( \alpha_2(t) \) = two different phase factors of the two lasers, respectively. For broadband lasers, \( \alpha_1(t) \) and \( \alpha_2(t) \) are uncorrelated, and they vary rapidly and randomly. The last term at the right-hand side of Equation 63.7 can contribute to \( I \) only in a time-averaged way, and the time average of this term is zero. For narrowband lasers, a beat is obtained at the differential frequency of the two lasers, and \( I \) varies sinusoidally in time for any fixed \( z_2 - z_1 \). The time average of the last term in Equation 63.7 is also zero. Thus, \( I \) always equals a constant of \( A_1^2 + A_2^2 \), no matter how \( |z_2 - z_1| \) is varied.

Multibeam Interference

Interference can occur among any number of beams obtained by splitting one laser beam. Let a laser beam with unit amplitude be split into \( N(N > 1) \) beams, the amplitudes of these \( N \) beams fall off progressively, and the phase difference between two successive beams be a constant \( \Delta\phi \). These beams can be described by \( E_k(z) = \rho^k \exp[-i \phi(z) - i k \Delta\phi + i \alpha(t)] \), where \( k = 0, 1, \ldots; N - 1 \), and \( \rho < 1 \). Then, these \( N \) beams are recombined. Multibeam interference occurs among these beams. The intensity of the recombination of these beams is given by:

\[
I = \left| \exp[-i \phi(z) + i \alpha(t)] \sum_{k=0}^{N-1} \rho^k \exp(-ik\Delta\phi) \right|^2 = \frac{1 + \rho^{2N} - 2\rho^N \cos(N\Delta\phi)}{1 + \rho^2 - 2\rho \cos(\Delta\phi)}
\]  

(63.8)
Equation 63.8 shows that $I$ is a function of $p$ and $N$, and is a periodic function of $\Delta \phi$. More information about the wave theory of light and light interference can be found in many advanced optics textbooks such as Reference 5.

**Diffraction Gratings**

A diffraction grating can spatially disperse a polychromatic laser beam into its monochromatic components and is the most widely used optical device for analyzing optical spectrum covering a relatively wide range. Several different types of diffraction gratings are available. A planar reflective diffraction grating is a collection of many small, identical and slit-shaped grooves ruled on a planar high reflective surface. **Figure 63.7** shows two grooves of such a grating, an incident laser beam with three wavelength components $\lambda_1 < \lambda_2 < \lambda_3$ and three diffraction beams marked by $m = 0, 1, 2$, respectively. The beams are in the plane defined by the grating normal and the groove normal. The grooves illuminated by the incident beam generate diffraction beams with the same amplitude since the grooves are identical. Multibeam interference occurs among the diffraction beams. The phase difference $\Delta \phi$ between two adjacent diffraction beams of a grating is given by:

$$\Delta \phi = \frac{2\pi}{\lambda} d[\sin(\theta_1) + \sin(\theta_2)]$$

(63.9)

where $d = $ groove period, $\theta_1 = $ angle between the incident beam and the grating normal, $\theta_2 = $ angle between the diffraction beams and the grating normal ($\theta_2$ is not marked in Figure 63.7.), and $d(\sin(\theta_1) + \sin(\theta_2)) = $ path difference between two adjacent diffraction beams. Constructive interference among the diffraction beams occurs at

$$\Delta \phi = 2m\pi$$

(63.10)

where $m = $ an integer known as the diffraction order. Combining Equations 63.9 and 63.10 results in

$$d(\sin(\theta_1) + \sin(\theta_2)) = m\lambda$$

(63.11)

Equation 63.11 is known as the grating equation and shows that, for a given $\theta_1$ and $m$, $\theta_2$ is a function of $\lambda$. $\theta_2$ gives the diffraction beams a propagation direction in which $I$ has the maximum value. The

**FIGURE 63.7** Two grooves of a planar reflective diffraction grating. The grating disperses an incident beam containing three wavelengths, $\lambda_1 < \lambda_2 < \lambda_3$. There are three diffraction beams with diffraction order $m = 0, 1, 2$. 

© 1999 by CRC Press LLC
angular dispersion resolution of a grating is defined by $d\theta_2/d\lambda$, and can be obtained by differentiating equation (63.11). The result is:

$$\frac{d\theta_2}{d\lambda} = \frac{m}{d\cos(\theta_2)}$$

(63.12)

where $\theta_1$ is assumed to be a constant. Large $d\theta_2/d\lambda$ is often desired and can be obtained by the use of a small $d$, a large $\theta_2$ close to $90^\circ$, and a large $m$. Usually, $\theta_2$ must be smaller than $80^\circ$ to maintain the proper functioning of the grating and $d = \lambda$; Equation 63.11 shows that the largest possible value of $m$ is 2. Equations 63.11 and 63.12 also show that $m = 0$ leads to $\theta_2 = -\theta_1$ and $d\theta_2/d\lambda = 0$. That means that, in the zero diffraction order, the grating does not disperse the incident beam, and all the diffraction beams propagate in the same direction, $\theta_2 = -\theta_1$. Commonly used diffraction gratings have a groove density from 300/mm ($d \approx 3.33\,\text{mm}$) to 2400/mm ($d \approx 420\,\text{nm}$). The corresponding dispersion resolution for $m = 1$ is from $d\theta_2/d\lambda = 4 \times 10^{-4}\,\text{rad}/\text{nm}$ to $d\theta_2/d\lambda = 3.4 \times 10^{-3}\,\text{rad}/\text{nm}$. The intensity of the diffraction beams of a grating can also be described by Equation 63.8 with $p = 1$. That is:

$$I = \frac{\sin^2\left(\frac{N\Delta\phi}{2}\right)}{\sin^2\left(\frac{\Delta\phi}{2}\right)}$$

(63.13)

Equation 63.13 is plotted in Figure 63.8 for $N = 5$ and 20, respectively. Equation 63.13 shows that $I$ is a periodic function of $\Delta\phi$. $I$ reaches maximum of $N^2$ at $\Delta\phi = 2m\pi$ and zero at $\Delta\phi = 2k\pi/N$ ($k$ is any integer, but $k \neq mN$). The fringe width $\Delta\phi_w$ of $I$ is given by

$$\Delta\phi_w = 2\left[2m\pi - \frac{2(mN - 1)\pi}{N}\right] = \frac{4\pi}{N}$$

(63.14)

Equation 63.14 shows that the resolution of a grating is proportional to $N$, since the resolution can be defined as $1/\Delta\phi_w$.

Most advanced optics textbooks (e.g., Reference 5) study gratings, and manufacturers’ catalogs (e.g., Reference 6) give a product-oriented description of gratings.
Monochromators

Monochromators are instruments widely used for optical spectrum analysis. Various types of monochromators have been developed. Figure 63.9 shows the scheme of a simple monochromator. The laser beam under measurement is incident through the entrance slit, two concave spherical mirrors collimate the beam, the grating disperses the beam, then one concave spherical mirror focuses the beam on the exit slit, and a laser power meter measures the power of the beam passing through the exit slit. The grating is mounted on a rotator. The position of the two slits are fixed. For any given grating orientation, θ₁ and θ₂ are known. The wavelength λ of the diffraction beams passing through the exit slit can be calculated using Equation 63.11. By rotating the grating and recording the power measured as a function of the corresponding λ, we can measure the spectrum. The widths of the two slits are Δs₁ and Δs₂, respectively, and are adjustable. The three mirrors image the entrance slit on the exit plane. The image width Δs₁’ of the entrance slit is proportional to Δs₁. Equation 63.15 gives the measurement resolution of a monochromator:

$$\Delta s \frac{d\lambda}{ds} = \frac{\Delta s d\lambda}{f d\theta_2}$$  \hspace{1cm} (63.15)

where \(d\lambda/ds\) is the linear dispersion resolution, \(\Delta s\) equals the larger of \(\Delta s_1\) and \(\Delta s_2\), \(d\lambda/d\theta_2\) is the inverse of the angular resolution of the grating used, and \(f\) is the focal length of the focusing mirror. Equation 63.15 shows that reducing the widths of the two slits can increase the measurement resolution. However, the slits must be wide enough to allow enough laser power passing through for measurement. The grating rotation angular resolution also affects the measurement resolution of a monochromator. The resolution of commonly used monochromators is from 0.1 to 1 nm. Monochromators usually have a moderate price and measurement resolution. A product-oriented description of monochromators can be found in manufacturers’ catalogs such as Reference 7.

Scanning Fabry-Perot Interferometer

Another widely used optical spectrum analyzer is a scanning Fabry-Perot interferometer (SFPI). An SFPI consists of two slightly wedged transparent plates with flat surfaces as shown in Figure 63.10. The two inner surfaces of the plates are set parallel to each other and are high-reflecting coated. The distance \(D\) between the two inner surfaces can be adjusted by a piezoelectric device. The two outer surfaces have a

![FIGURE 63.9 Scheme of a simple monochromator.](image)
small angle between them, so that reflections of the two outer surfaces can not interfere with the reflections of the two inner surfaces. The medium between the two plates is usually air with a unit refractive index. The laser beam under measurement is collimated by a lens and incident on the SFPI. The beam transmitted through the SFPI is focused by another lens onto the photodetector of a laser power meter. When a beam with unit amplitude is incident at angle \( \theta \) on the inner surface of an SFPI, multiple reflections take place at the two inner surfaces and produce a series of transmitted beams whose amplitudes fall off progressively. In Figure 63.10, only three incident rays with a few reflections are plotted. The phase difference between two successive transmitted beams is:

\[ \Delta \phi = \frac{4\pi D}{\lambda \cos(\theta)} \]  

(63.16)

Interference occurs among the amplitude of the transmitted beams. The intensity of the combination of the transmitted beam is given by:

\[ I = \left| T \sum_{k=0}^{\infty} R^k \exp(-ik\Delta \phi) \right|^2 \]  

(63.17)

where \( R \) and \( T = 1 - R \) = the power reflectivity and transmission coefficient of the inner surfaces of the SFPI, respectively, and the reflectivity of the outer surfaces of the SFPI is neglected. The laser power meter measures the power of the transmitted beams. Note that Equation 63.8 can be reduced to Equation 63.17 by letting the amplitude \( \rightarrow T, \rho \rightarrow R < 1, \) and \( N \rightarrow \infty \). Therefore, the \( I \) obtained in Equation 63.17 can also be described by the curve shown in Figure 63.8. The full width at half the maximum (FWHM) power of \( I \) can be found by solving Equation 63.17. The result is:

\[ \Delta \phi_{\text{FWHM}} = 4\sin^{-1}\left(\frac{1 - R}{2R^{1/2}}\right) \]  

(63.18)

When \( R \) is close to 1, the right-hand side of Equation 63.18 is close to zero. We have:

\[ \Delta \phi_{\text{FWHM}} = \frac{2(1 - R)}{2R^{1/2}} \]  

(63.19)

\[ \text{FIGURE 63.10} \] Scheme of a scanning Fabry-Perot interferometer. Only three incident rays and a few reflections are plotted.

© 1999 by CRC Press LLC
Equation 63.19 shows that the fringe width of $I$ reduces as $R$ is increased, because larger $R$ results in more reflections between the two inner surfaces of the SFPI. In an SFPI, the beam is usually arranged to incident at normal on the inner surface. $\theta$ becomes zero. Combining Equations 63.10 and 63.16 results in:

$$\lambda = \frac{2D}{m}$$

(63.20)

where $\lambda$ is the wavelength at which the peak of $I$ appears. Figure 63.8 shows that an SFPI functions like a multibandpass filter. The central wavelengths of the bands (fringes) are given by Equation 63.20 and can be adjusted by adjusting $D$. The FWHM of the bands is given by Equation 63.19. The spacing between two adjacent bands in terms of wavelength can be obtained by differentiating Equation 63.20 with respect to $m$, eliminating $m$ and letting $\Delta m = 1$. The result is:

$$\Delta \lambda = \frac{\lambda^2}{2D}$$

(63.21)

$\Delta \lambda$ is known as the free spectral range (FSR) of an SFPI. The laser beam under measurement must have a wavelength bandwidth smaller than the FSR to ensure that the beam can transmit only through one band. When $D$ is scanned, the transmitted wavelength is scanned, and the laser power meter measures and outputs the beam spectrum. The measurement resolution of an SFPI is limited by $\Delta \phi_{\text{FWHM}}$. Most SFPIs have an $R > 0.95$ to reduce the $\Delta \phi_{\text{FWHM}}$. The characteristics of an SFPI can be described by the fringe finesse $F$, defined as:

$$F = \frac{2\pi}{\Delta \phi_{\text{FWHM}}} = \frac{\pi R^{1/2}}{1 - R}$$

(63.22)

where $2\pi$ is the period of the fringes given by Equation 63.10 in terms of phase. An SFPI usually has a resolution of FSR/100. For $\lambda = 500$ nm and $D = 5$ mm, the FSR is 0.025 nm, and the resolution is 0.00025 nm. Compared with monochromators, SFPIs are more expensive, and they have much higher resolution and a much smaller wavelength range.

More information about SFPIs can be found in many advanced optics textbooks such as Reference 5 and Chapter 6.5 of this handbook. A product orientated description of Fabry-Perot interferometers can be found in manufacturers’ catalogs such as Reference 8.

### 63.4 Measurement of Laser Wavelength

For single-mode and narrow-linewidth lasers, the spectrum measurement reduces to wavelength measurement. Laser wavelength can be measured to a higher accuracy by the use of techniques that are not much different from those used to measure the spectrum. A laser wavemeter is an instrument designed to measure the wavelength without knowing the details of the spectrum.

**Michelson CW Laser Wavemeter**

**Figure 63.11** shows the scheme of a widely used Michelson CW laser wavemeter that consists of a Michelson interferometer (MI), a laser power meter, and a computer system for data processing. The MI has two optical arms formed by a beam splitter and two mirrors, respectively. Mirror $M_2$ can be moved by a stepper motor driving system, and thereby the arm length $z_2$ can be changed. The position of mirror $M_2$ is fixed, and the arm length $z_1$ cannot be changed. Two lenses collimate the laser beam under measurement. The beam splitter splits the collimated beam into two. The two beams propagate in the
two arms and are reflected by the two mirrors back to the beam splitter, respectively. Then the beam splitter recombines the two beams. Interference occurs between these two beams. Another lens focuses the combined beams onto the photodetector of a laser power meter. The computer system processes the output data of the laser power meter. The intensity $I$ of the two combined beams can be described by Equation 63.6. As $M_1$ is moved, $z_1$ is changed, the path difference $|z_2 - z_1|$ between the two optical arms varies, and $I$ varies periodically. The computer counts the number of the varying period of $I$, known as counting the fringes. Equation 63.23 relates the wavelength $\lambda$ under measurement, $M_1$ moving distance $L$, and the counted fringe number $m + \Delta m$ by:

$$(m + \Delta m)\lambda = 2L$$

(63.23)

where $m = \text{an integer}$, $\Delta m = \text{a fraction}$, and the factor of 2 is introduced because the beam round trip distance is considered. A He-Ne laser with accurately known wavelength $\lambda_H$ is used as a calibration source. For the He-Ne laser, there is the relation:

$$(m_H + \Delta m_H) = 2L$$

(63.24)

where $m_H$ is another integer and $\Delta m_H$ is another fraction. Combining Equations 63.23 and 63.24 results in:

$$\lambda = \frac{m_H + \Delta m_H}{m + \Delta m} \lambda_H$$

(63.25)

For $L = 500$ mm and $\lambda = 500$ nm, Equations 63.23 and 63.24 give $m = 2 \times 10^6$ and $m_H = 2 \times 10^6$. If $\Delta m$ and $\Delta m_H$ can be counted to an accuracy of 0.1, Equation 63.25 can provide six significant digits. Thus, $\lambda$ can be calculated to a relative accuracy of about $10^{-6}$. The commonly used commercial Michelson CW laser wameteters have a relative measurement accuracy from $10^{-4}$ to $10^{-7}$. The measurement range is usually from 400 nm to 1.1 mm, limited by the spectral range of the silicon photodetector used.

Steadily moving $M_1$ over a distance of 500 mm or so can take several seconds, and the computer is counting fringes during the entire moving period of $M_1$. Several seconds is much longer than the pulse duration of most pulsed lasers. Thus, the computer will miss fringes in the period of time between two successive pulses when measuring the wavelength of a pulsed laser, and the measurement result will be erroneous. To measure the wavelength of pulsed lasers, the laser wavemeter must not have any moving parts and must be capable of taking data instantaneously.

More information about MIIs can be found in many advanced optics textbooks such as Reference 5 and Chapter 6.5 of this handbook. Reference 9 presents a comprehensive study about the design and development of a MI CW laser wavemeter that achieves an accuracy of a few parts in $10^6$. 

FIGURE 63.11 Scheme of a Michelson CW laser wavemeter.
Pulsed Laser Wavemeter

Figure 63.12 shows the scheme of a Fizeau pulsed laser wavemeter, which consists of a Fizeau wedge, a charge coupled device (CCD) linear sensing array with 1024 pixels, a computer system for data processing, and an optical collimation system. The Fizeau wedge is made of a transparent material such as glass. The wedge has two flat surfaces. The angle $\alpha$ between the two surfaces is a few milliradians. The optical thickness $l(x)$ of the wedge is about 2 mm and varies linearly along the wedge. The optical system collimates the laser beam under measurement. The collimated beam is incident on the wedge. Both surfaces of the wedge reflect the incident beam. The two reflected beams form tens of spatial interference fringes on the CCD array. The CCD array detects the interference fringes and sends the data to the computer for processing. A Fizeau wavemeter does not have any moving parts and can measure the wavelength of pulsed lasers. It can be shown that the fringe period $p$ is proportional to the wavelength $\lambda$ under measurement by:

$$p = F_1(\alpha)\lambda$$  \hspace{1cm} (63.26)

where $F_1(\alpha)$ is a function of $\alpha$. A He-Ne laser with accurately known wavelength $\lambda_H$ is used separately as a calibration source. The He-Ne laser also forms spatial interference fringes on the CCD array with a fringe period $p_H$ proportional to $\lambda_H$ by:

$$p_H = F_1(\alpha)\lambda_H$$  \hspace{1cm} (63.27)

The data processing algorithm used in Fizeau wavemeters has two steps. $\lambda$ is first calculated by combining Equations 63.26 and 63.27:

$$\lambda_1 = \frac{\lambda_H}{p_H}$$  \hspace{1cm} (63.28)

In Equation 63.28, the symbol $\lambda_1$ denotes the wavelength calculated in the first step because $\lambda_1$ is still not accurate enough. The data processing algorithm can calculate the fringe period $p$ and $p_H$ to an accuracy of higher than $10^{-4}p$ and $10^{-4}p_H$ utilizing the 1024 sensing data provided by the CCD array. Thus, Equation 63.28 can provide $\lambda_1$ to an accuracy higher than $10^{-4}\lambda_1$, and $\lambda$ must fall somewhere inside the range:

$$\lambda_1 - 10^{-4}\lambda_1 < \lambda < \lambda_1 + 10^{-4}\lambda_1$$  \hspace{1cm} (63.29)

FIGURE 63.12 Scheme of a Fizeau pulsed laser wavemeter.
Any point on the CCD array corresponds to a point on the wedge with a certain optical thickness \( l(x) \). It can be shown that at a given point on the CCD array, there is such a relation for \( \lambda \) and \( \lambda_H \) that:

\[
(m + \Delta m)\lambda = F_2[l(x)] \quad (63.30)
\]

\[
(m_H + \Delta m_H)\lambda_H = F_2[l(x)] \quad (63.31)
\]

where \( m \) and \( m_H \) are two integers and are unknown, \( \Delta m \) and \( \Delta m_H \) are two fraction orders at this point on the CCD array and can be measured, \( F_2[l(x)] \) is a function of \( l(x) \), and \( l(x) \) is the thickness of the wedge at the point corresponding to the point on the CCD array. In the second step of the data processing, \( \lambda \) is calculated by combining Equations 63.30 and 63.31. The result is:

\[
\lambda_2 = \frac{m_H + \Delta m_H}{m + \Delta m} \lambda_H \quad (63.32)
\]

In Equation 63.32, we use the symbol \( \lambda_2 \) to denote the wavelength calculated, because \( \lambda_2 \) is still not necessarily equal to \( \lambda \). A number of test \( m \) and \( m_H \) values are inserted into Equation 63.32 and result in a number of different \( \lambda_2 \) values. It can be shown that only one combination of \( m \) and \( m_H \) can result in a \( \lambda_2 \) that falls inside the range of Equation 63.29. This \( \lambda_2 \) is accepted as \( \lambda \). \( m \) and \( m_H \) are of the order of \( 10^5 \), and \( \Delta m \) and \( \Delta m_H \) can be measured to an accuracy of 0.01. Therefore, Equation 63.32 can provide \( \lambda \) to an accuracy of \( 10^{-6} \). The commercial Fizeau pulsed wavemeters have a measurement accuracy of \( 10^{-5} \). The measurement spectral range is from 400 nm to 1.1 \( \mu \)m, limited by the CCD array, which is made of silicon material. More information about Fizeau wedges can be found in many advanced optics textbooks such as Reference 5 and Chapter 6.5 of this handbook. Readers interested in learning more about the design and development of Fizeau pulsed wavemeters will find Reference 10 to be a good starting point.

### 63.5 Instrumentation and Components

Table 63.1 lists a few companies manufacturing photodetectors, laser power meters, diffraction gratings, monochromators, scanning Fabry-Perot interferometers, Michelson CW laser wavemeters, and Fizeau pulsed laser wavemeters. The price ranges of these instruments and components are also listed in Table 63.1. Table 63.2 lists the address of these companies. These two tables are far from exhaustive. Interested readers could consult two excellent books, *Laser Focus World Buyers Guide* [11] and *Photonics Buyers’ Guide* [12]. These two books are published annually and contain up-to-date information about most optical and laser manufacturers in U.S.A and their products.

63.6 Defining Terms

**Continuous wave (CW) laser power:** Laser power that does not vary with time.

**Pulsed laser power:** Laser power that lasts only a short period of time.

**Laser spectrum:** Laser power-wavelength profile.

**Laser wavelength:** The spatial period of a laser electric field.

Vision is the act of seeing, a human capability derived from the combination of the image forming optical system of the eye, the array of light sensitive receptors in the retina of the eye, and the information processing capacity of the retina and human brain. Applications for instruments with a similar ability to sense a scene include broadcast television, monitoring industrial processes, quality control during manufacture, viewing inaccessible or hazardous places, aiding medical diagnosis, and remote sensing from satellites and space probes, to name but a few. Each application often has particular requirements more critical than others, and the problem is to find the most economical solution satisfying these most closely.

The human eye is a familiar imaging system, highly optimized to aid survival under the naturally occurring range of illumination conditions. It is useful to describe its basic characteristics [1] to provide a benchmark against which machine vision can be compared. Light intensity can be measured using radiometric quantities such as radiant power, which is the radiant energy transferred per second in watts; irradiance, which is the radiant power falling onto a surface of unit area in W/m²; and radiance, which is the radiant power leaving unit area of a surface per unit solid angle in W/st/m². It can also be measured using photometric units that take into account the variation in response of a standard human eye with wavelength, the CIE (Commission Internationale de l’Eclairage) response curve. The photometric equivalent of radiant power is luminous flux, measured in lumens (lm); the photometric equivalent of irradiance is illuminance, measured in lm/m² or lux; and the photometric equivalent of radiance is luminance measured in lm/st/m² or cd/m². At the wavelength of peak sensitivity (555 nm) in the CIE sensitivity curve, the conversion factor from radiometric to photometric units is 680 lm/W.

The eye has a response (observed brightness) to incident light intensity which is roughly logarithmic and is capable of adapting, given time, to an enormous range of different illuminance levels, from full sunlight (100,000 lux) to starlight (0.001 lux). The illumination generally recommended for surfaces in an office environment (about 100 lux) represents a comfortable working level. It takes about 30 min for
the eye to become fully dark adapted and a further 3 min to adapt again to increased lighting levels. Despite this adaption capability, when viewing any one point in a scene under bright light conditions, the eye is capable of discerning only about 25 different intensity levels. The eye achieves its enormous range of brightness adaptation partly through the action of a variable size iris (about 2 to 8 mm in diameter), but mainly through the presence of two types of light sensitive receptor in the retina of the eye.

At high illumination levels, corresponding to photopic vision, the eye perceives color due to the excitation of three different types of cone receptors. There is considerable overlap in the spectral sensitivity curves of these red, green, and blue receptors, which have peak responses near 600, 550, and 500 nm, respectively. The overall photopic response is greatest at a wavelength near 555 nm in the yellow green region of the spectrum and falls to zero toward the red and the blue ends of the spectrum at about 750 and 380 nm, respectively. At low levels of illumination, corresponding to scotopic vision, only the rod receptors are excited with a peak luminous efficiency of about 1700 lm/W near 510 nm in the green region of the spectrum. The sensitivity to contrast of the dark-adapted eye is much poorer than that of the light-adapted eye. The transition between photopic and scotopic vision is gradual, with both excited over a luminance range from about 0.001 to 0.1 cd/m². The photopic response extends higher to the glare limit, about five orders of magnitude brighter, while the scotopic response extends lower to the threshold of vision, about three orders of magnitude lower. The photopic (CIE) and scotopic spectral responses of the eye are shown in Figure 64.1 with the response of a typical silicon-based sensor for comparison. The latter has a spectral response that is quite different from that of the human eye, extending well beyond the red end of the visible spectrum toward 1100 nm, with maximum sensitivity around 800 nm. Assuming the average spectral response of silicon, an irradiation of 1 µW/cm² corresponds to an illumination of about 0.22 lux.

The distribution of the cones and rods over the inner surface of the eyeball is nonuniform, with the cones most densely packed in the region of the fovea, a circular region about 1.5 mm in diameter situated toward the rear of the eyeball. To achieve sharpest vision, the eye muscles automatically rotate the eyeball so that the object of interest in the scene is imaged onto the fovea. The separation of the approximately 400,000 cones in the fovea is such that a normal young eye is able to distinguish alternating black and white bands, each 1 mm wide at a distance of about 5 m, corresponding to an angular resolution of about 0.2 mrad. The resolution of the dark-adapted eye is very much poorer because, although the maximum number of rods per square millimeter is similar to that of cones, several rods are connected to a single nerve end, whereas only a single cone is connected to a nerve end.

The overall performance of the eye is difficult to equal. However, a machine vision system can surpass it in individual respects such as sensitivity to infrared and ultraviolet radiations invisible to the eye, speed of response (which can be as short as nanoseconds), and sensitivity to low light levels corresponding to the detection of individual photons of radiation over periods of several hours. Machine vision charac-

![Figure 64.1](image-url)
teristics depend on the type of image sensor employed and the modifying effects of additional components such as image intensifiers or optical fiber scopes. The machine vision equivalent of the eye includes a lens to project a 2-D image of the 3-D object of interest onto a sensor that transforms the light energy into an electrical signal. In this form, it may then be transmitted to a remote location, subjected to computer analysis, or displayed on a television screen. A rectangular 2-D image can be sensed using three different approaches. A single, small sensor can be moved in a zig-zag or raster fashion to sense the light intensity on a grid of points covering the whole image. A second approach is to use a line sensor composed of many individual sensors. If it is equal in length to one side of the image, it need only be moved in steps equal to the width of the individual sensors, a distance equal to the other side to cover the whole image. The third approach is to use an area sensor comprising a 2-D array of individual sensors. Whatever method is used, each individually sensed small region of the image is called a picture element or pixel and, in general, the resolution of the imaging system improves with increasing number of pixels. Although the first two methods require relative movement between sensor and scene, they are not limited by the sensor in the amount of resolution that can be achieved along the direction of motion. In addition, the inevitable variation in response between different sensors is easier to correct than with comparable area sensors, because there are fewer sensors. Two common applications of line sensors are monitoring objects on moving conveyer belts and scanning documents. In many cases, however, it is not practical to arrange relative movement of image and sensor, and the majority of image sensors in use are monochrome or color area sensors designed for use in television cameras. Monochrome and color cameras both use the same basic sensors, which have an inherently broad spectral response. Color sensitivity is achieved with the aid of color filters. A common approach is to deposit color filters directly on the sensor surface in a mosaic or stripe pattern. This is a cheap and compact solution but results in a lower spatial resolution in each color, compared with the resolution of the equivalent unfiltered sensor, and loses much of the incident light through absorption in the filters. Better sensitivity and resolution are obtained using three-sensor cameras that incorporate an optical arrangement (based on dichroic mirrors) that separates the incident light into three components—say red, green, and blue—which are each directed at a different sensor. However, this approach is both bulky and expensive, because it requires three sensors rather than one, and precision optics to align the images correctly on the individual sensors.

Most area sensors currently sold are designed to produce electrical signals compatible with either the 525-line American television standards (RS-170 for monochrome and NTSC for color) or the 625-line European television standards (CCIR for monochrome and PAL for color) [2]. These are interlaced television standards in which each complete image or frame is made up of two fields, each containing either odd or even numbered lines from the frame. Half the remaining lines, making up the odd total number in the frame, appear in each field, ensuring that the two fields interlace properly on the television display. Interlacing is used to avoid picture flicker without having to double the rate of information transmitted. According to the Ferry-Porter law, the critical frequency below which flicker is observed depends on the logarithm of the luminance of the picture highlights. At the brightness levels corresponding to normal viewing, flicker would be observable in pictures interrupted at 25 Hz or 30 Hz, but it is reduced to an acceptable level at the repetition rates of the fields (60 Hz for NTSC and 50 Hz for PAL). A consequence of the Ferry-Porter law is that an NTSC picture can be about six times brighter than a PAL picture and still be acceptable in terms of flicker. Many companies supply frame grabber computer boards that sample the TV-compatible voltage signals (about 1 V range) at a frequency of at least 10 MHz (for at least 512 samples per line), quantize the analog voltage to 256 or more discrete levels (8 bits), and store the resulting digital data for computer analysis. Interlaced operation is not ideal for some applications and, at higher cost, cameras are available that provide higher frames rates, higher resolutions, or progressive scan (no interlacing). These usually produce a standard digital output signal for easy input into a computer. A very wide range of sensors and cameras are currently commercially available, based on several different types of technology. Although each technology has particular advantages, the characteristics of different devices based on a specific technology can vary significantly. For example, the spectral responses of photodiode-based sensors generally extend to shorter wavelengths than those of CCD (charge-coupled device)-based sensors, but some CCD devices are available with extended blue-
end responses. Improved and/or cheaper sensors and cameras are appearing on the market all the time and, when considering a new imaging system, it is wise to review the characteristics of the devices currently available in comparison with the requirements of the application in order to select the most suitable. One of the first steps in the creation of a machine vision system for a new application is the design or selection of an appropriate optical system, and this is the subject of the next section. Later sections discuss the various sensor technologies that are available and other related devices that can be used to improve sensitivity or to allow image sensing in restricted spaces such as body or machine cavities.

### 64.1 Image Formation

The machine vision optical system has the tasks of matching the required field of view to the dimensions of the sensor and gathering sufficient light to achieve a sensor signal that has adequate signal-to-noise ratio (SNR) while maintaining the image sharpness required by the application. Resolutions of area sensors are sometimes specified by manufacturers as the maximum number of horizontal TV lines that can be distinguished. This value may be obtained from measurements of the visibility of a test chart (EIA test pattern), or it may simply be the number of horizontal pixels divided by 1.33, in the case of a monochrome sensor. In special circumstances, measurements to subpixel accuracy can be achieved by interpolation between pixel values, and Reference 3 describes the measurement of a knife edge to about 0.1 pixel accuracy. As a rule of thumb, however, for size measurement applications, the sensor should have a number of pixels at least equal to twice the ratio of the largest to smallest object sizes of interest [4], and a lens is then selected to provide the required magnification and working distance. A lens operating in a single medium such as air is characterized [5] by two focal points and two principal planes as indicated in Figure 64.2. The principal planes coincide with the lens center in the case of an ideal thin lens but may be separated by +20 to –10 mm (the negative sign indicating reversed order), depending on the design, in multielement lenses. They can be determined by first locating the two focal points and then measuring along the axis from these, distances equal to the focal length. A lens of focal length \( f \) produces an image in best focus at a distance \( l_i \) when the object is at distance \( l_o \) where

![Figure 64.2](image-url)  
**Figure 64.2** The trace of a ray from a distant object through a typical multielement lens system showing typical positions of focal points and principal planes. The distance from the back focal length to the lens flange mount is 17.3 mm for C-mount lenses, 12.5 mm for CS-mount lenses, and 46.5 mm for 35 mm photographic format Nikon F (bayonet) mount lenses. Adapters are available to accommodate the differences in distances and fittings of the different mounting systems.
and the distances are measured to the corresponding principal planes. The image magnification \( m \), defined as the ratio of image to object size, is equal to the ratio of the image to object distances and is related to the total distance between object and image \( D_T \) by

\[
D_T = \frac{F(m + 1)^2}{m} + D_N
\]  

(64.2)

where \( D_N \) is the separation between the principal planes. Lenses generally have a focusing adjustment of 5 to 10% of the focal length, and extension rings between the lens and sensor are required for image magnifications greater than about 0.05. The lens extension required is simply the product of the magnification and the focal length. The depth of field \( F_o \) of an imaging system [6] is the displacement of the object along the optic axis that produces no significant degradation in the sharpness of the image. The corresponding movement of the image is the depth of focus. In the case of a lens with \( f \)-number \( f_\#{\text{}} \) (equal to the ratio of focal length to lens iris diameter) and an image sensor with pixel size \( P \), it is given by

\[
F_o = 2f_\# \frac{P(m + 1)}{m^2}
\]  

(64.3)

Television cameras sensors are manufactured to standard sizes such as 1, 2/3, 1/2, or 1/3 in. The size is defined to be twice the horizontal dimension of a rectangular image with 4:3 aspect ratio so that a 1-in. sensor has a width of 12.7 mm, a height of 9.5 mm, and a diagonal length of 15.9 mm. Lens sizes are similarly specified to allow easy matching of lenses to sensors. Because image distortion and sharpness worsen toward the edges of the field of view, it is permissible, for example, to use a 2/3-in. lens with a 1/2-in. sensor, but not the converse. A 35-mm camera lens, designed for a 24 by 36 mm image size, generally performs much better, at relatively low cost, than a corresponding C-mount lens supplied for a TV camera but a C-mount to Pentax, Cannon, or Nikon mount converter will then be required.

It is frequently necessary to relate lighting of a scene to camera sensitivity. Accurate calculations are difficult, and it is usually better to make a simple estimate and then make fine adjustments to the lighting or lens aperture. Manufacturers often specify camera sensitivities by quoting an illumination level in lux at the sensor faceplate. This may be the illumination required to achieve maximum signal output, some proportion of this maximum, or simply a “usable” signal level from the camera. The illumination of the sensor \( L_s \) in lux is related to the luminance of the object \( B \) in cd/m\(^2\) by

\[
L_s = \frac{TB\pi}{[2f_\#(m + 1)]^2}
\]  

(64.4)

where losses in the lens are characterized by a transmission coefficient \( T \). If the object is a uniform diffuse reflector (Lambertian surface) illuminated by \( L_o \) lux, then the luminance of the object is given by

\[
B = L_o\frac{R}{\pi}
\]  

(64.5)

where \( R \) is the reflection coefficient of the surface. Some practical examples of radiometric calculations are given in a Dalsa application note [7].
64.2 Image Sensing

The primary functions occurring within a standard image sensor are the conversion of light photons falling onto the image plane into a corresponding spatial distribution of electric charge, the accumulation and storage of this charge at the point of generation, the transfer or readout of this charge, and the conversion of charge to a usable voltage signal. Each of these functions can be accomplished by a variety of approaches, but only the principal sensor types will be considered here. Sensors can be divided into two groups: (1) vacuum tube devices in which the charge readout is accomplished by an electron beam sweeping across the charge in a raster fashion similar to that in a television picture tube, and (2) solid-state devices based on charge-coupled devices or photodiodes. These three types of sensor will be described in the next three sections.

Television Camera Tubes

For many years, vacuum tubes [8] provided the only technology available for television applications, and they are still widely used because of the high-quality image signals they provide. Companies supplying tubes include Burle and Philips. Most modern tube cameras are based on the vidicon design whose basic components are indicated in Figure 64.3. Light from the scene is imaged by a lens onto a photoconductive target formed on the inner surface of an end window in a vacuum tube. An electron gun is placed at the opposite end of the tube to the window, and it provides a source of electrons that are focused into a beam, accelerated toward the target by a positive potential on a fine mesh placed just in front of the target, and scanned across the target by an electrostatic or magnetic deflector system. The target consists of a glass faceplate on the inner surface, upon which is placed a transparent electrically conducting coating of indium tin oxide. On top of this is deposited a thin layer of photoconductive material in a pattern of tiny squares, each insulated laterally from its neighbors. The transparent coating is connected to a positive voltage through an electrical load resistor across which the signal voltage is developed. In the absence of

FIGURE 64.3 A schematic diagram of the major components of a vidicon camera tube. Many variants of this basic design exist utilizing different target materials to improve particular characteristics. The electron beam readout of the optically generated charge in the target makes the tube bulky and less reliable than solid-state sensors. Most tubes currently sold are for replacement in existing equipment rather than in new cameras, which almost always incorporate solid-state sensors.
light, the electron beam causes the external surface of the photoconductor to be charged to near zero potential. Light causes the resistance of the photoconductor to decrease, and its surface to acquire a more positive potential, due to the accumulation of positive charge. At each point on the surface touched by the electron beam, some of the beam current is deposited to neutralize the positive charge present due to the illumination. The rest passes through the load resistor generating an output voltage that is a function of the light intensity at that point. The precise timing of the scanning process ensures that the location of the beam is known at each instant in time.

Vidicons have some unique characteristics. They can have spectral responses extending into the ultraviolet and infrared regions of the spectrum, and they allow scan rate and adjustments in scan alignment to be made electronically by adjusting the scanning pattern. This allows very simple region-of-interest readouts. On the other hand, the electron beam readout method confers a number of disadvantages, which are not found in solid-state devices, including large size, fragility, susceptibility to shock and vibration, high power consumption and a high degree of sensitivity to external electric and magnetic fields. The principal imaging defects, which again are not present in solid-state devices, include

- lag when displaying changing images, due to slow response speed,
- image burn which is damage to the sensor surface caused by intense light,
- geometric distortion,
- drift in the apparent position of the image,
- a nonlinear relationship between signal output and light intensity which varies with target voltage.

The degree to which these effects are present depends on the type of tube and its particular construction.

The original vidicon tube design employed antimony trisulphide as the photoconductive material and a low-velocity electron beam and gave only adequate performance. Newer tubes employ the same basic design but use better electron beam readout techniques and target materials to improve characteristics such as spectral response, sensitivity, dark current, lag, and burn-in. Two tubes suitable for broadcast television use are the plumbicon developed by Philips and the saticon introduced more recently by Hitachi. The plumbicon employs a lead-oxide photoconductive target, while the saticon target comprises several layers with different combinations of selenium, arsenic, and tellurium. It can provide greater resolution than the plumbicon, but the lag performance and range of operating temperature are worse. Examples of nonbroadcast quality tubes are the newvicon, chalnicon, and the si-vidicon. The newvicon target has a double layer of cadmium and zinc tellurium, which achieves exceptional sensitivity, but lag and nonuniformity are excessive. The chalnicon employs a cadmium selenide target and provides good performance in most respects but has excessive lag. The si-vidicon target effectively consists of an array of silicon photodiodes that are reverse biased and store charge released by the incident light. The resulting tube has very high sensitivity and little lag, and it is virtually burn proof. However, it exhibits excessive blooming and nonuniformity. The silicon-intensified camera, or SIT camera, is a modification of the si-vidicon camera that employs a photocathode that generates electrons when struck by light photons. These electrons are accelerated by a voltage of several hundred volts and focused on the target of the si-vidicon sensor that produces an output in the normal way. The high-speed electrons landing on the target produce large numbers of electron-hole pairs and a corresponding larger response. The resulting SIT sensor is used in very low light level applications such as tracking satellite debris and can produce useful video images at illumination levels down to 0.001 lux. By comparison, a solid-state CCD sensor (without an image intensifier) typically requires about 1 lux to produce a useful video signal.

**Charge-Coupled Devices**

A CCD is fabricated on a single crystal wafer of $p$-type silicon and consists of a one- or two-dimensional array of charge storage cells on centers typically about 10 µm apart. Each cell has several closely spaced electrodes (gates) on top, separated from the silicon by an insulating layer of silicon dioxide. The charge is stored under one of the electrodes, and its location within the cell is defined by the pattern of positive voltages applied to the electrodes. By applying a coordinated sequence of clock pulses to all the electrodes...
in the array, packets of stored charge (of between 10 and 10^6 electrons) are transferred from one cell to the next until they finally reach a sensing amplifier (floating gate diffusion) which generates a voltage signal proportional to charge, usually assumed to be 1 µV per electron. The result is a device that has an inherently linear variation of output voltage with light from the minimum useful level set by noise, to the maximum useful level set by saturation of the output amplifier, or the limited capacity of the charge storage cells. The dynamic range of the device is defined as the ratio of the maximum output signal to the output resulting from noise. Manufacturers published figures may use peak-to-peak or root-mean-square noise values (typically five times smaller) in this calculation, but the former is more relevant for imaging applications.

Any light penetrating into the underlying silicon generates electron-hole pairs. The holes are swept away to the substrate electrode while the electrons accumulate beneath the nearest electrode in a potential well created by the applied voltage. The sensitivity of silicon is of the order of 1 µA of generated charge per microwatt of incident light. The cells intended to function as light-sensitive photosites have electrodes made of semitransparent polysilicon so that the light can penetrate into the storage region, whereas those intended to function only as part of a shift register for charge transfer are covered by an opaque surface layer. Due to manufacturing imperfections, the photosites do not have perfectly uniform characteristics, and a photoresponse nonuniformity (PRNU) of about 5 to 10% is fairly typical. This is easy to measure using uniform sensor illumination and its effects can be removed if necessary by calibration. The basic spectral response of the silicon extends from 200 to 1100 nm, but the first figure is typically reduced to 450 nm by absorption in the surface layers of the CCD photosites. Infrared radiation penetrates deeper into the silicon than shorter wavelengths, and charge created by an infrared photon may be collected by a different cell to the one entered by the photon. This reduces the resolution of the device, and if infrared operation is not required but the illumination contains infrared (from a tungsten lamp for example), then an infrared reflecting filter (a hot-mirror filter) is often used. CCD cells also accumulate charge linearly with time due to thermally generated electrons produced within the cells and at electrode interfaces. Like the photoresponse, this dark signal varies from cell to cell and can be compensated for by calibration. These thermally generated contributions are most significant for low light level applications and can be reduced by cooling the sensor using either a thermoelectric cooler, a Joule Thomson cooler, or a liquid nitrogen dewar. The dark signal reduces by 50% for every 7°C reduction in temperature, and at –60°C, produced by a Peltier cooler, the dark signal is typically reduced to about one electron per pixel per second. Another important temperature dependent characteristic of the CCD sensor which improves with cooling is the noise floor of the output amplifier which is proportional to \( T^{1/2} \) and typically equivalent to about 300 electrons at room temperature. A particular CCD device used in astronomy, for example, and operated at about –110°C has a readout noise of about 10 electrons, a dark current less than 0.3 electrons per minute, and a quantum efficiency for converting visible photons into electrons of between 70 and 80%. Light can be integrated for periods of hours, compared with the approximately 1/8 to 1/4 s integration period of the dark-adapted eye. Compared with photographic film previously used for low-light level imaging in astronomy, CCDs are from 10 to 100 times more sensitive, linear in response rather than nonlinear, and have a much greater dynamic range so that both faint and bright objects can be recorded in the same exposure.

The short-exposure, high-frequency performance of CCD devices is limited by another effect. The process of transporting charge in a CCD sensor is not 100% efficient and, in practice, a small amount of charge is left behind at each transfer to the next cell, contributing noise and degrading resolution. This effect limits the maximum clock frequency and the maximum number of transfers in a CCD sensor. Manufacturers’ data sheets for commonly available CCD sensors quote values ranging from 0.9995 to 0.99999 for the charge-transfer efficiency or CTE of a single transfer. There are many variations in CCD technology. For example, virtual-phase CCDs [9] have some of the electrodes replaced by ion-implanted regions, resulting in improved blue response and higher sensitivity because of the removal of some of the blocking surface gates, and simpler drive circuitry because of the reduction in number of gates per cell. A manufacturing technique known as pinning can be used to passivate the interface states, which are the biggest contribution to the dark signal, producing an order of magnitude improvement in dark
signal as well as improved quantum efficiency and CTE. A signal-processing technique called *correlated double sampling* can also be applied to the output signal from the sense amplifier to improve the readout noise performance.

**Linear Charge-Coupled Devices**

The basic structure of a linear CCD sensor is shown in Figure 64.4. It consists of a line of up to several thousand photosites and a parallel CCD shift register terminated by a sensing amplifier. Each photosite is separated from a shift register cell by a transfer gate. During operation, a voltage is applied to each photosite gate to create empty storage wells which then accumulate amounts of charge proportional to the integral of the light intensity over time. At the end of the desired integration period, the application of a transfer pulse causes the accumulated charge packets to be transferred simultaneously to the shift register cells through the transfer gates. The charges are clocked through the shift register to the sensing amplifier at a rate of up to 20 MHz, producing a sequence of voltage pulses with amplitudes proportional to the integrated light falling on the photosites. In practice, it is common for shift registers to be placed on both sides of the photosites, with alternate photosites connected by transfer gates to the right and left registers. This halves the number of cells in each register and the time required to clock out all the data. Another 2× reduction of transfer time is achieved if each shift register is split into two with an output amplifier at each end. There is a limit, typically between $10^5$ to $10^6$ depending on photosite size and dimensions, to the number of electrons that can be stored in a particular cell, beyond which electrons start to spill over into adjacent cells. The saturation charge in electrons is roughly 1000 to 2000 times the area of the photosite in square micrometers. This spread of charge or blooming is a problem with images containing intense highlights. It is reduced by about a factor of 100 by adding antiblooming gates between adjacent photosites and transfer gates and channel stops between adjacent photosites. The voltage on the antiblooming gates is set at a value that allows surplus charge to drain away instead of entering the transfer gates and shift register. By clocking this voltage, variable integration times that are less than the frame pulse to frame pulse exposure time can also be attained.

**Area Charge-Coupled Devices**

Three basic architectures are used in area CCDs and are illustrated in Figure 64.5. The simplest is the full-frame CCD, consisting of an imaging area separated from a horizontal CCD shift register by a transfer gate.
In the imaging area, each photosite is one stage of a vertical shift register separated from neighboring shift registers by channel stops and antiblooming structures. During the light integration period, the vertical clocks are stopped, creating potential wells which collect photoelectrons. At the end of this period, the charge in the horizontal shift register is then very rapidly shifted toward the output amplifier by the application of a horizontal clock signal. An example full-frame CCD is the RA1001J from EG&G Reticon, which has pixels arranged in a $1024 \times 1024$ configuration and dual horizontal shift registers and outputs to achieve a 30 frame per second readout rate. To avoid image smearing during the readout period, full-frame CCD sensors must be operated with external shutters, as in digital cameras produced by Kodak and other companies, or used in low light level applications requiring very long integration times compared with the readout time, as in astronomy. The full-frame CCD is also the basis for time delay and integration (TDI) sensor manufactured by companies such as Dalsa and EG&G Reticon. In the application of this device, which may have 96 rows each with 1024 pixels, a moving scene illuminates a region on the sensor only one pixel high, and this is arranged to move vertically down the sensor at the same rate that the generated photocharge is shifted down the sensor. This mode of operation achieves an output signal identical to that from a linear CCD sensor except for a increased light sensitivity proportional to the number of horizontal rows in the TDI sensor. It can be appropriate in applications where both high speed and high sensitivity are required, providing a cheaper alternative to the combination of a line sensor and an image intensifier. An application of this technique to capturing images of web systems moving at up to 5 m/s is described in Reference 10.

The requirement for an external shutter is greatly reduced in the frame-transfer CCD sensor by the provision of a light-shielded storage section into which the entire two-dimensional image charge is shifted at a much higher rate (limited primarily by CTE considerations) than is possible in a full-frame CCD. The charge can then be read from the storage region during the next integration period without any further image smearing. Some sensors, such as the EG&G Reticon RA1102 device, have the storage area divided into halves placed on opposite sides of the imaging area. This improves performance by halving the maximum number of transfers required to reach the nearest storage region. The same reduction

FIGURE 64.5 The basic architectures used in area CCDs. FF devices fully utilize the available area for image detection and therefore achieve the largest number of pixels, currently about $5000 \times 5000$, but need an external shutter. FT devices are normally used at standard video rates without an external shutter. The ILT architecture allows exposure times down to less than 0.1 ms. The lower fill factor of ILT devices compared with FF and FT devices results in higher values of modulation-transfer-function at the Nyquist limit. This increases the visibility of aliasing artefacts in images containing high spatial frequencies. A low-pass optical filter must be used if aliasing is a problem.
occurs automatically in sensors designed for interlaced video applications where each integration period corresponds to one video field, and only half the number of rows in the frame is required at any one time. For example, to produce an interlaced video frame containing 576 image lines (CCIR standard), a frame transfer sensor with only 288 rows of storage is required. By changing the clock signals, the odd field can be displaced vertically by half a line width relative to the even field. This ensures that the odd and even lines contain different information and reduces aliasing, because the cell width is twice the separation between the lines in the frame. Some of the companies that produce frame-transfer CCD sensors and cameras include Cohu, Dalsa, EG&G Reticon, EEV, Kodak, Philips, and Thomson-CSF.

Image smear is virtually eliminated by the interline-transfer (ILT) architecture in which each column of photosites has an adjacent light-shielded vertical CCD shift register into which the charge is transferred by a transfer pulse. The contents of all the vertical shift registers are then shifted simultaneously one pixel at a time into a horizontal shift register where they are then rapidly shifted to an output amplifier. This approach makes it easy to implement exposure control and achieve short integration times, but it introduces dead space between the active pixels, reducing the sensitivity of the image sensing area and increasing aliasing effects compared with frame-transfer sensors. For the latter, the fill factor, which is the percentage of the imaging area which is light sensitive, can be close to 100%, whereas it is usually less than 50% for interline-transfer devices. Localized bright objects tend to produce vertical streaks in an ILT device because strong light can leak under the narrow light shield covering the vertical shift registers, causing image smearing similar to that in a full-frame device. This reduces the usefulness of ILT sensors for scenes containing pronounced highlights. For interlaced operation, two adjacent pixels, for example 1 and 2, 3 and 4, etc., are transferred to a single shift register cell on one field, and in the next field pixels 2 and 3, 4 and 5, etc., are transferred together. This is rather similar to the interlaced operation of a frame transfer CCD. The primary advantages of the ILT sensor are low noise and good exposure control, providing true stop-motion control on every field, because all photosites integrate light over the same period of time. Many companies manufacture ILT CCD sensors and cameras, including Hitachi, NEC, Panasonic, Pulnix, and Sony.

The frame transfer and interline transfer approaches both have performance advantages and disadvantages, and the hybrid frame-interline transfer (FIT) approach [11] combines some of the advantages of both. This architecture includes a light-shielded field storage area between an interline imaging area and the horizontal output shift register. With this arrangement, the charge associated with the whole image is first transferred horizontally into the interline storage area, which facilitates exposure control. The charge is then transferred at maximum speed (as in the FT sensor) into the field storage area, which minimizes the occurrence of vertical streaking. For example, the NEC microPD 3541 array clocks the vertical registers at 100 times the normal rate for an ILT sensor. This gives a 20-dB improvement in streaking threshold and an overall threshold of 80 dB, making streaking effects less than other optical effects such as lens flare. On the other hand, the FIT approach does not improve the fill factor, and aliasing artefacts associated with ILT sensors and the noise levels are somewhat higher, and the CTE reduced, because of the higher clock frequencies. Manufacturers of FIT sensors and cameras include JVC, Panasonic, and Sony.

**Photodiode Arrays**

Because photodiode arrays generally have less extensive electrode structures over each sensing element compared with CCD arrays, the spectral response is smoother and extends further at the blue end of the spectrum. The peak quantum efficiency is also higher ranging from 60 to 80% compared with 10 to 60% for photogates, leading to almost twice the electric output power for a given light input power. Photodiode arrays would therefore appear to be attractive alternatives to CCD array sensors but, in practice, CCD sensors have lower noise levels because they do not have reverse-bias leakage current. A photodiode consists of a thin surface region of P-type silicon formed in an N-type silicon substrate. A negative voltage applied to a surface electrode reverse-biases the P-N junction and creates a depletion region in the N-silicon containing only immobile positive charge. When the electrode is isolated, the P-N junction is left
charged and is effectively a charged capacitor. Light penetrating into the depletion region creates electron-hole pairs which, with dark current, discharge the capacitor linearly with time. The penetration depth in silicon increases with wavelength and the depletion region should be wide enough to absorb all wavelengths of interest. Dark current and most of the noise sources operating in the photodiode increase with reverse bias but can be reduced by employing a thicker P-type region which allows a wide depletion region to be achieved with low bias voltage. However, this also degrades the blue-end response of the photodiode. To achieve good blue and UV response along with low bias voltage operation, a three-layer structure comprising thin P-type, intrinsic, and N-type substrates is employed. The intrinsic layer is so pure that the depletion region extends halfway across it at zero bias and extends right across it at a small reverse bias voltage. This structure provides photodiodes with excellent linearity, noise performance, and speed of response at low operating voltages. At the end of an integration period, the states of charge of the photodiodes are measured, and image sensors based on two different types of readout approach are commercially available. These are the serially switched (sometimes called self-scanned) photodiode (SSPD) arrays and the charge-coupled photodiode (CCPD) arrays illustrated in Figure 64.6.

Serially-Switched Photodiode Arrays

Associated with each photodiode in the sensor array is an MOS (metal-oxide semiconductor) switch which, when turned on by a digital voltage level applied to its control line, connects the photodiode to a readout amplifier. Each control line is connected to one of the outputs of a digital shift register and, shifting a bit through the register, sequentially reads the charge on each photodiode in the array. This type of readout is very flexible, and random readout is achieved by replacing the digital shift register by an address decoder connected to an address bus as in the SR series linear arrays from EG&G Reticon. 2-D arrays of photodiodes are connected in a configuration similar to a cross-point switching matrix with a switch and diode at each cross point and separate vertical and horizontal shift registers. To scan the array, the vertical shift register turns on a complete row of switches, which causes the photodiodes in the corresponding row to dump their charge into vertical signal lines. These are in turn connected to the output amplifier by a set of horizontal switches controlled by the horizontal shift register. Switched arrays of photodiodes are made using processes similar to those employed in the manufacture of dynamic RAM, and this along with their simple structure and small size, yields higher densities and lower manufacturing costs. However, the SSPD approach has one shortcoming, namely the large capacitances of the readout buses. This reduces the speed of the device, increases the noise, and reduces the dynamic range, which are all generally significantly worse than those of CCD sensors. The dynamic range for

![Figure 64.6](image-url) Readout architectures associated with photodiode array sensors. In the SSPD approach shown, each photodiode is connected in turn via an MOS switch to the sensing amplifier. This eliminates smearing, because the charge does not move between photosites. The device noise and speed characteristics are poorer than CCD sensors because of nonuniformity in the MOS switches and the large capacitance of the sensing bus. The CCPD approach combines the excellent blue end response of the photodiode with the low noise transfer characteristics of the CCD shift register to produce very high-quality linear devices.
example is typically 250 to 300 compared to more than 2500 for commercially available CCD sensors. SSPD arrays also suffer from fixed-pattern noise due to nonuniformities in the switches, which can be as high as 20% of the saturated output. The SSPD approach does have unique advantages:

- The readout method is extremely flexible and can be programmable.
- It is relatively free from blooming effects, because the sensors can be optimally isolated from each other.
- The blue response is good, which is particularly important for spectroscopic applications and for studio quality color television cameras.

Manufacturers supplying SSPD-based sensors include EG&G Reticon, Hamamatsu and VLSI Vision.

Charge-Coupled Photodiode Arrays

Although individual photodiode elements are superior to individual CCD photogate elements in terms of dynamic range, the dynamic range of the SSPD is limited by fixed pattern noise, switching noise and the difficulty of transferring charge packets over the high capacitance output bus. Replacing the horizontal digital shift registers by a low noise CCD shift register significantly improves the dynamic range of the device and the resulting hybrid design is the charge-coupled photodiode array. During operation, the charges on an entire row of photodiodes are simultaneously transferred via MOS switches into the analog CCD shift register and then shifted out in sequence to the output amplifier. By providing a reset pulse (from a second vertical digital shift register) to eliminate all pre-stored charge in one row a fixed interval before the charge is transferred to the CCD shift register, it is relatively easy to implement an electronic equivalent of a focal plane shutter [12] and control exposures in increments of one horizontal scan period. However, images of moving objects will be subject to distortions similar to those found using photographic cameras with focal-plane shutters. In the case of 2-D arrays there are inefficiencies in the movement of small charge packets over the vertical transport lines which get worse the smaller the packet. The solution adopted is to turn a small charge into a large one by pre-charging the lines with a priming charge equal to 10 to 15% of the maximum charge capacity before transferring the photo-charge to the CCD in a process known as charge-primed transfer. This requires several MOS switches forming a sequence of transfer gates and storage capacitors between each vertical transport line and CCD cell and depends critically on correct phasing of a large number of timing signals for proper operation. The CCPD approach appears to be most successful for linear arrays which do not require a vertical transport bus. Manufacturers supplying linear CCPD based sensors include Dalsa and EG&G Reticon.

64.3 Image Intensifiers

When the available solid-state image sensors do not have enough sensitivity for the scene illumination, it is necessary either to use a more sensitive tube camera or to amplify the available light. Companies supplying intensified cameras include Cohu, Kodak, Pulnix, and Philips. Intensified cameras are standard video cameras fitted with image intensifiers that increase the number of available photons falling onto the image sensor. In addition to allowing operation over a wide range of lighting of the order of 0.0001 lux from overcast starlight to 100,000 lux of full sunlight, intensified cameras can be used to stop motion in nanosecond frame times, count photons, and observe images with very high intrascene dynamic ranges. However, this increased flexibility is achieved at a considerable increase in cost, usually some loss in resolution, reduced lifetime, and increases in geometrical distortion, lag, and smear. Image intensifier tubes (IITs) are usually classified as generation I, II, and III devices.

Generation I Tubes

In a generation I intensifiers, illustrated in Figure 64.7, the incoming photons strike a multialkali photocathode within a vacuum tube, and the resulting photoelectrons emitted into the vacuum are accelerated and focused onto a phosphor coating on the rear wall of the tube. The impact of the high-energy
electrons on the phosphor creates many electron-hole pairs that in turn generate light at a higher level than that striking the photocathode. The electron gain depends strongly on the accelerating voltage and also on the photocathode and phosphor materials, and it is typically around 200 with a 12 kV accelerating voltage. These tubes tend to be bulkier than later-generation tubes and have relatively low gains, although tubes can be cascaded to achieve higher gains. They are also relatively intolerant of bright sources and rapid changes of scene illumination, with increased tendency toward highlight blooming. The light output from the intensifier tube is transferred to the solid-state sensor by either a relay lens or a fiber-optic coupler. The latter is shorter and much more efficient (typically 60% compared with 6%), but requires a sensor whose protective glass or quartz window has been replaced by the fiber-optic coupler resting against the sensor surface. The narrow gaps between couplers and between the coupler and sensor are filled by an index-matching optical grease. The spectral response of the photocathode should be chosen to match the scene requirements, while the narrower phosphor response should be optimally matched to the image sensor for greatest sensitivity [13]. In general, for largest output, a phosphor with the maximum persistence that is acceptable in terms of image lag should be selected. But, if the scene includes object motion, a shorter-persistence phosphor may be necessary to avoid image smear. For night vision, P20 and P39 phosphors are frequently used. The former emits 550 nm light with very high luminous efficiency (65%) and relatively short persistence (0.2 ms), while the latter has a persistence of about 80 ms, which reduces high-frequency jitters. For high-speed imaging, the yellowish-green P46 phosphor has a persistence of only 0.16 µs, while the purplish-blue P47 phosphor has a persistence of only 0.08 µs. However, both these phosphors have luminous efficiencies of only 3%. The resolution of an intensified camera is generally quoted in line pairs per millimeter (lp/mm) and is the harmonic mean of the individual resolutions of the intensifier (typically 20 to 30 lp/mm), the coupler (typically 80 lp/mm), and the image sensor (typically 20 to 50 lp/mm).

**Generation II and III Tubes**

Generation II intensifiers are similar to generation I devices except that gain is achieved using a microchannel plate (MCP) instead of an accelerating potential difference in vacuum (see Fig. 64.8). Generation III intensifiers are similar to generation II except that the multialkali photocathode is replaced by a gallium arsenic solid-state structure. The resulting device has double the gain of a type II device and improved SNR and resolution. The heart of both types is an MCP disk about 25 mm dia. and 0.5 mm thick, consisting of an array of millions of glass tubes (called microchannels) with holes about 10 µm diameter.
coated with a secondary electron emitting substance. The two faces of the MCP are coated with conducting layers, allowing a voltage (typically 50 to 900 V) to be applied between the entrance and exit of each microchannel. An energetic electron from the photocathode enters a microchannel and produces secondary electrons on striking the wall. These electrons are accelerated by the axial electric field and, in turn, dislodge more secondary electrons. This process is repeated many times down the channel. The number of electrons continues to increase until either the end of the channel is reached or current saturation occurs because the electron cloud is so dense that it inhibits further secondary emission. The electrons exit the MCP and may be accelerated further before striking a phosphor screen. The light generated is then transported to the image sensor by fiber-optic couplers. A thick phosphor layer increases light gain but allows electrons and light scattering in the phosphor, which causes some loss of resolution. Improved performance is achieved by integrating the phosphor into the fiber-optic bundle in a so-called intagliated construction. Each glass core in the fiber-optic bundle is etched out to a predetermined depth, leaving a small cup of cladding glass at the entrance to each fiber, which is filled with phosphor. Electrons striking the phosphor produce light that is confined to one fiber, minimizing crosstalk and improving resolution. The overall light amplification achieved is of the order of $10^4$, and higher gains can be achieved by stacking multiple MCPs and by increasing the accelerating voltages. The MCP has a nonlinear response, because the current density increases at an exponential rate until limited by saturation. The IIT can be gated in only a few nanoseconds by pulsing the cathode potential from the cutoff level (a few volts positive) to the normal operating voltage. This provides a high-speed shutter capability for stopping motion as well as a means of exposure control. Generation II devices have high gain and dynamic range and are easy to gate on and off, but they have relatively low output levels compared with generation I devices. The Kodak EktaPro 1000 high-speed video camera uses a generation II intensifier as a high-gain first stage coupled to a generation I intensifier to provide the required level of light output.

FIGURE 64.8 The basic components of a generation II or III intensified-image sensor. These are typically two and four times more sensitive than generation I intensifiers. Narrow vacuum gaps between the photocathode, microchannel plate, and phosphor screen achieve proximity focusing. An example is the Philips I8000 low-light video camera, which couples an XX1410 generation image intensifier with an FT800 1/2-in., 760 × 576 resolution frame-transfer CCD at a cost of around $8000.

64.4 Fiber Optic Scopes

It is sometimes necessary to acquire images within confined and inaccessible spaces. In some cases, this can be achieved with the aid of mirrors, but when the image must be conducted around bends, a fiberscope may be needed. This consists of a semirigid flexible sheathing around a bundle of optical fibers, each about 10 µm diameter aligned coherently so that fibers have the same relative location at entrance and exit of the bundle. An image formed on one end of the bundle therefore appears undistorted but dimmer
at the other end. Between 20 and 35% of the bundle face area consists of fiber cladding and epoxy filler and does not transmit light. Light passing through fiber cores suffers Fresnel reflection losses of about 4% on entering and leaving, and attenuation within the fibers of the order of 10 to 15% for each meter of length. A 1 m fiberscope therefore transmits only about 40 to 60% of the incident light. Fiberscopes range in diameter from about 2 to 18 mm and in length from about 0.6 to 3 m, with a minimum bend radius of about 75 mm for an 8 mm insertion diameter tube. To illuminate the object, a coaxial arrangement of fibers is often used, as in the flexible boroscope marketed by Edmund Scientific. The inner fibers are used for imaging, while fibers in the outer, noncoherent bundle are used to transport light to the object. Alternatively, a separate fiber-optic light guide may be used. Fiberscopes may be fitted with optics for viewing in the forward, oblique, side, and rearward directions but may not allow easy quantitative measurements of distances and areas because of distortions introduced by wide-angle optics. Fiberscopes are generally supplied with an eyepiece for direct observation, but C-mount couplers are often available to allow a CCD camera to be connected.

### 64.5 Components and Trends

A wide range of image sensors and cameras based on tube and solid-state technologies is now available, and a few examples are listed in Table 64.1 to give an indication of some of the currently available devices and their approximate prices, if purchased in the U.K. It is advisable to contact local suppliers to determine actual prices and availability. Contact information for some companies is listed in Table 64.2. Manufacturers are continuing the incremental development of sensors with greater resolutions, readout rates, and signal-to-noise performances, and new application areas such as high-definition television (HDTV) and digital photography should cause prices to come down as the markets for these products expand. Some examples of this type of development are as follows.

- EG&G Reticon is currently developing a 1000 frames per second, $1024 \times 1024$ interline-transfer CCD sensor for high-speed imaging.

- Thomson Components (France) has developed the THX-31163 CCD sensor specifically for use in HDTV. This chip is designed to output $1152 \times 1260$ pixel frames in 40 ms at a transfer frequency of 47 MHz.

- Manufacturers such as Kanimage, Kodak, and Leaf Systems supply digital cameras based on very high-resolution area array sensors. The Kodak professional range of color and monochrome digital cameras, for example, incorporate CCD full-frame transfer sensors with resolutions ranging from $1024 \times 1536$ to $2036 \times 3060$ into standard 35 mm photographic cameras.

A separate trend is the development of smart cameras and smart sensors [14] for industrial and scientific applications. There are two basic motivations. One is to correct for imperfect behavior of sensors (such as pixel to pixel nonuniformity associated with MOS devices), and the other is to reduce the communications or processing bottlenecks associated with handling very large amounts of image data. A smart camera is a single-image acquisition subsystem incorporating image sensor, analog-to-digital conversion, and microprocessor that provides processed image data in a standard format such as SCSI or RS-423. Pulnix already supply a series of smart linescan cameras that implement application functions such as object detection, size measurement, and go, no-go comparison. Another example is the imputer 3 [15] from VLSI Vision incorporating a CMOS (complementary MOS) area sensor with $512 \times 512$ digital resolution and an i960 32-bit reduced instruction set processor. Using VLSI technology, but not CCD technology, it is possible to integrate both image acquisition and low-level processing onto a single chip to achieve a kind of electronic retina. One way of constructing such chips is to integrate photodetector and processing element at the photosite, but this produces very poor fill factors. This can be alleviated to some extent by using microlenses to focus the light onto the sensitive region. An alternative approach is to implement the photodetection and processing as separate arrays on the chip. This allows a large fill.

65.1 Radioactivity

Radioactivity is the phenomenon of emissions of neutral or charged particles, or electromagnetic radiations from unstable atomic nuclei. The more common types of radiations are listed in Table 65.1. Several naturally occurring (primordial) radionuclides and some produced by cosmic rays in the earth's atmosphere are given in Table 65.2. Methods of producing other unstable nuclei are discussed below. Radioactive isotopes from man-made sources and from naturally occurring nuclides are widely used in health sciences, industry, and academic research.

Radioactivity was first discovered by Henri Becquerel in 1896. His student Marie Curie and her husband Pierre Curie were the first to chemically separate the radioactive elements polonium and radium. Becquerel and the Curies received the Nobel Prize in physics in 1903 for their pioneering work in nuclear and radiochemistry. The historical development of the field of radioactivity is covered in a number of

standard texts, including *The Atomic Nucleus* [1] and *Radioactivity and Its Measurement* [2], and in *Radioactivity Measurements: Principles and Practice* [3]. Other excellent texts are available for students in nuclear medicine [4], in radiochemistry and nuclear chemistry [5, 6], in nuclear and particle physics [7, 8], and a popular general textbook *Radiation Detection and Measurement* by Knoll [9] for nuclear engineering and health physics.

Radioactivity is defined by the International Commission on Radiation Units and Measurements [10] in terms of the *activity*, $A$, of an amount of a radionuclide in a particular energy state at a given time. Mathematically, it is defined as the quotient of $dN/dt$, where $dN$ is the number of spontaneous nuclear transformations from that energy state in the time interval $dt$, thus

$$A = \frac{dN}{dt}$$

The unit of activity in the International System (SI) of units is the becquerel (Bq), which is equal to the unit reciprocal second ($s^{-1}$). In many fields the older unit, the curie (Ci), is still in use, where 1 Ci = $3.7 \times 10^{10}$ Bq (exactly).

The activity of an amount of radionuclide is given by the product of the decay constant, $\lambda$, and the number of nuclei present at time $t$, thus

$$A = \lambda N$$

The reciprocal of $\lambda$ is the mean life of the nuclide. More commonly, one computes the time necessary for one half of the nuclei to decay, and since this is an exponential process, the half-life is given by

$$T_{1/2} = \frac{\ln 2}{\lambda} = \frac{0.69315}{\lambda}$$

The activity at any time $t$ can be computed using the initial activity $A_0$ and the decay time $t$ according to

$$A = A_0 \exp\left(-0.69315 \frac{t}{T_{1/2}}\right)$$

The term *specific activity* is in use in several applied fields and one should be careful to look at the units in any particular application. It is normally defined in terms of the amount of activity per unit mass of the element. For example, the nominal activity of $^{14}$C in modern carbon (that found in the biosphere) is 0.3 Bq g$^{-1}$. In nuclear medicine, however, specific activity is widely used to express the amount of activity per unit quantity of the radioactively labeled compound. For example, one might

produce $^{11}$C in a cyclotron and oxidize it to carbon monoxide CO with a specific activity of 1 MBq $^{11}$C \( \mu \text{mol}^{-1} \) (CO) (megabecquerel of activity per micromole of substance).

Stable nuclei are those nuclei in their ground state that have a proper number of neutrons and protons to balance the nuclear forces between constituents and thus do not decay spontaneously. Radioactive nuclei may be divided into three categories:

- those that have an excess of neutrons over protons,
- those that are neutron deficient, and
- those that are in excited nuclear states.

A schematic showing the most prominent simple transformations between elements of atomic number \( Z \) and neutron number \( N \) are given in Figure 65.1. The atomic number \( Z \) is the number of protons, and the isotopic mass number \( A \) is the total number of nucleons (protons plus neutrons). The notation for an isotope—for example, one of krypton—is $^ZKr$. In this chapter, isotopes will be identified only by the mass number and the element symbol, e.g., $^{241}$Am.

**Particle Emission Radioactivity**

**Alpha particles** are $^4$He nuclei (2 protons plus 2 neutrons) and are usually emitted by heavy nuclei ($A > 150$). Alpha particles are monoenergetic and usually have energies between 4 and 6 MeV. Table 65.3 lists several alpha emitters, including some at lower and higher energies that can be used for the energy calibration of instruments. Alpha particles carry a +2 charge, and their detection with a variety of instruments is described in detail in Chapter 67, on charged-particle detectors. Alpha-particle pulse-height distributions for several radionuclides of interest in the nuclear fuel cycle are shown in Figure 65.2. The alpha-particle pulse-height distribution for an $^{241}$Am source obtained with a high-resolution detector is given in Chapter 66 (Figure 66.16).

Beta particles are high-energy electrons emitted by the nucleus as a result of the "weak force" interactions in nuclei that contain too many or too few neutrons. For a system with excess neutrons, the neutron is transformed into a proton and in the process an electron and an antineutrino $\bar{\nu}$ are emitted

$$n \rightarrow p + e^- + \bar{\nu}$$

The proton remains behind in the nucleus. The antineutrino is required to maintain the conservation of momentum, energy, and "weak-interaction" quantum numbers with respect to the emitted electron [5]. The emitted negatively charged beta particles, usually denoted as $\beta^-$, have a continuum of energies from zero to a maximum energy denoted by $E_{\beta_{\text{max}}}$. $E_{\beta_{\text{max}}}$ is the total energy available for the kinetic energy of the electron. The antineutrino carries away that portion not transferred to the electron. An example of an emission spectrum for $^{32}$P is given in Figure 65.3. The mode of decay for neutron deficient nuclei is quite similar, except that the proton is converted to a neutron with the emission of a positive electron or positron ($\beta^+$) and a neutrino, which may be written as

FIGURE 65.2 Liquid-scintillation spectra of selected actinides using a single-phototube detector with the peak channel counts for each major peak preset to 40,000 counts [11].

Although it is unusual, some radioisotopes decay by both negatron β− and positron β+ emission. For example, in the decay of the 13-day half-life $^{126}\text{I}$ one has

$$^{126}\text{I} \rightarrow ^{126}\text{Te} + e^+ + \nu$$

(65.7)

$$^{126}\text{I} \rightarrow ^{126}\text{Xe} + e^- + \overline{\nu}$$

(65.8)

Table 65.4 gives a short list of pure beta-particle emitters.

a. These nuclides exhibit a small amount of electron-capture (EC) decay.

**Neutrons** are constituents of the nucleus that have a mass number of unity and carry no charge. In normal radioactive decay processes, neutrons are not emitted from the nucleus. With energies exceeding...
a few million electron volts (MeVs), however, one can add sufficient energy to cause a neutron to be ejected from the nucleus. These energies can be attained by bombardment with alpha particles from radioactive decay, which is the basis for the common neutron source Americium-Beryllium (AmBe) in which the alpha particles from the $^{241}$Am induce neutron emission from the $^9$Be nucleus:

$$^{241}\text{Am} \rightarrow ^{237}\text{Np} + \alpha$$  \hspace{1cm} (65.9)

$$\alpha + ^9\text{Be} \rightarrow ^{13}\text{C*} \text{ (excited state)}$$ \hspace{1cm} (65.10)

$$^{13}\text{C*} \rightarrow \begin{cases} ^{12}\text{C*} + n \\ ^8\text{Be} + \alpha + n \\ 3\alpha + n \end{cases}$$ \hspace{1cm} (65.11)

In this case, the $^{13}$C nucleus is formed in a highly unstable excited state and rapidly disintegrates by several processes, all of which lead to neutron emission. The neutron spectrum from a $^{241}$AmBe source is shown in Figure 65.4. It is very difficult to measure neutron spectra directly, because it is necessary to deconvolve a complicated detector response. Figure 65.4 is the “standard” spectral shape recommended in recent national and international standards [13, 14]. The units on the $y$-axis are explained in Reference 13.

Neutrons are also readily produced in high-energy particle accelerators. Various combinations of accelerated particles and target materials are used to produce neutron beams with selected energies (e.g., 2 and 14 MeV). Neutrons from isotopic sources, accelerators and nuclear reactors can then be used in such applications as boron neutron capture therapy to treat cancer, or in metal fatigue analysis. The neutrons can also be used to produce radionuclides for other applications. **Protons** with unit positive charge and unit mass number are simply $^1$H nuclei stripped of the single orbital electron. Spontaneous emission of protons by nuclei is an exotic decay mode that has been

**FIGURE 65.4** Neutron spectrum of an $^{241}$AmBe radioisotopic source as given in the American National Standard [13] and the International Standard [14]. The units used on the $y$-axis are explained in Reference 13.
observed in only a few cases involving extremely neutron-deficient nuclei [15]. However, beams of protons can be made in positive-ion, charged-particle accelerators by injecting high-purity hydrogen gas, stripping the electrons, and then accelerating the protons to high energies. When these protons are incident on stable target nuclei, a variety of nuclear reactions are possible. The product nuclides are normally radioactive and neutron deficient.

**Fission fragments** are the large-mass debris formed when a high-Z nuclide such as $^{235}\text{U}$ spontaneously (or by absorption of a slow neutron) breaks up into two or more smaller nuclides in a process known as nuclear fission. The best known fissionable nuclei $^{235}\text{U}$ and $^{239}\text{Pu}$ fission as a result of capturing a neutron. For a given nucleus, the fission fragments are distributed according to a mass distribution which has two maxima. For $^{235}\text{U}$ fission, the maxima occur at $A = 90$ and $A = 130$, resulting in fission-product radionuclides such as $^{90}\text{Sr}$, $^{95}\text{Zr}$, $^{131}\text{I}$ and $^{137}\text{Cs}$. A small number of high-Z radionuclides decay by spontaneous fission (e.g. $^{248}\text{Cm}$). This decay process usually competes with alpha-particle decay and is mostly limited to high-Z nuclides.

### Electromagnetic Emission Radioactivity

**Gamma rays** are photons emitted during nuclear deexcitation processes. These gamma-ray transitions may be from a metastable excited state, or between levels in a daughter nucleus. Two examples are shown in Figure 65.5 for the 6-hour half-life $^{99m}\text{Tc}$ and the 2-day $^{111}\text{In}$. The large majority of gamma rays from fission products and man-made radionuclides have energies between 20 keV and 2 MeV. A list of gamma-ray emitters used for instrument calibrations are given in Table 65.5. The probability of gamma-ray emission in a particular radionuclide decay ($P_g$) is also given in the table. The rate of gamma-ray emission is given by the product $P_g A_0$.

![Figure 65.5](image.png)

**FIGURE 65.5** Simplified nuclear decay schemes for the radionuclides $^{99m}\text{Tc}$ and $^{111}\text{In}$. The vertical arrows indicate transitions between nuclear excited states. Gamma-ray emission competes with internal conversion processes for each transition [8].

© 1999 by CRC Press LLC
Characteristic **X-rays** are photons emitted during atomic relaxation processes. X-rays are emitted from radionuclides when electrons are involved in the high-energy processes in the nucleus. In the electron capture process, for example, the nucleus captures an electron (usually a K-shell electron, since it is closest to the nucleus), and a proton and electron form a neutron. This process leaves a K-shell vacancy, and a characteristic X-ray from the daughter nucleus can be emitted as orbital electrons from higher shells fill the vacancy. An example is the decay of the 2.6-year half life $^{55}\text{Fe}$

$$^{55}\text{Fe} + e^- \rightarrow ^{55}\text{Mn} + X \quad (65.12)$$

The rate of Mn K X-ray emission from an $^{55}\text{Fe}$ source of activity $A_0$ is

$$N_K = P_{KX} A_0 \quad (65.13)$$

where $P_{KX}$ = probability of K X-ray emission.

Conversion electrons are monoenergetic electrons emitted from the nucleus in isomeric transitions between nuclear levels. Conversion-electron emission competes with gamma-ray emission as a mode of nuclear deexcitation.

**Interactions with Matter**

Before examining in detail the manner in which ionizing radiations can interact, consider two sources of photon radiations, annihilation radiation and bremsstrahlung, which are associated with radioactive decay but depend on the material in which the decay process occurs.

**Annihilation radiation** is a form of photon radiation associated with a class of radioactive decays. Positrons, since they are the antiparticles of ordinary electrons, cannot survive long in normal matter. Thus, positrons emitted during radioactive decay will slow down in matter until they reach thermal equilibrium. (Depending on the matter, they may exist for some microseconds in a state of matter known as positronium.) Ultimately, they combine with an electron in an annihilation event in which their combined mass (1.022 MeV) is converted to energy. This takes the form of two annihilation quanta of 0.511 MeV each which are oppositely directed (to ensure the conservation of momentum). Depending on the positron energy and the density and thickness of the stopping material, there is a slight but calculable probability of annihilation in flight [1]. These decays do not result in characteristic 0.511-keV quanta.

**Bremsstrahlung** is the photon radiation emitted by the deceleration of an electron in the Coulomb field of an atom. Thus, bremsstrahlung radiation is present during all beta decay processes as the emitted $\beta$ particles (both negatrons and positrons) slow down in matter; it has a continuum of photon energies extending up to the maximum beta-particle energy. The shape of this continuum depends on the nature of the stopping material, as is described in the following section. Bremsstrahlung radiation represents a
particular safety hazard for high-energy pure-beta particle emitters such as $^{32}$P (14.4 day, 1.710 MeV $\beta^-$ max). At higher energies, bremsstrahlung production is almost linear in electron energy and proportional to $Z^2$ of the stopping material. Thus, to minimize bremsstrahlung, one uses low-Z shielding materials such as plastic.

Now, consider the more general ways in which ionizing radiations from radioactive decay interact with matter. They interact by collisions with the electrons and nuclei along their path. The nature of these interactions is characterized by the charge, mass, and energy of the incident ionizing photon or particle, as well as the charge and mass of the traversed matter. In the energy region of interest, electromagnetic radiation (gamma-ray and X-ray photons) interact with matter principally by three processes: photoelectric absorption, Compton scattering, and pair production. In the photoelectric process, which dominates at lower energies, the photon transfers its energy to an atomic electron, which is then ejected from the atom with an energy equal to that of the incident photon minus the electron's binding energy. In Compton scattering (incoherent scattering), the photon loses a fraction of its energy to an atomic electron, and the scattered photon emerges generally in a direction different from that of the incident photon. Higher-energy photons will undergo multiple Compton scatter events until the process is finally terminated by a photoelectric absorption. For photons with energies exceeding 1.022 MeV, the process of pair production can occur whereby an electron-positron pair is formed. The positron produced will ultimately annihilate with the production of two 0.511-MeV photons (or in flight). The three interaction processes compete as a function of photon energy, electron density, and nuclear charge of the stopping material. Above 2.044 MeV, triplet production can occur [16], but this is a low-probability process, and few radionuclides emit gamma rays above 2 MeV.

Quantitative measures of the photon interactions in matter are attenuation coefficients based on cross sections for specific interactions [8,9]. The total narrow-beam attenuation coefficient $\mu$ is given by the sum

$$\mu = \mu_{\text{photoelectric}} + \mu_{\text{Compton}} + \mu_{\text{pair production}}$$

The attenuation process for a beam of photons traversing a slab of matter is an exponential function of the form

$$I = I_0 \exp(-\mu l)$$  \hspace{1cm} (65.14)

where $I$ and $I_0$ = intensities of the transmitted beam and the incident beam, respectively, $l$ = distance traveled in matter, and $\mu$ = the linear attenuation coefficient. A useful procedure is to express distances in terms of the mass thickness—the product of density $\rho$ and thickness $l$. The beam transmission equation can then be rewritten as

$$I = I_0 \exp\left[-\frac{\mu}{\rho}l\right]$$  \hspace{1cm} (65.15)

where $\mu/\rho$ is the mass attenuation coefficient. The mass attenuation coefficient, in contrast to the linear attenuation coefficient, does not depend on the density of the absorber, but only on its composition. The mass attenuation coefficient as a function of energy for water and lead are shown in Figures 65.6 and 65.7. This discussion of photon interactions has been limited to narrow-beam (or ideal) geometries. In practice, most radioactive sources emit a broad beam of radiation such that the detector registers not only events from the incident beam but also those scattered through large angles, and these effects must be included in computing detector response [9].

Charged particles interact with matter in many different ways. These include:

1. inelastic collisions involving ionization and excitation of atomic electrons of the material
2. inelastic collisions involving bremsstrahlung production in the field of the atom
3. elastic scattering in the field of the atom
4. nuclear reactions
5. emission of Cerenkov radiation (photons in the visible and ultraviolet regions)

Electrons and positrons, due to their much smaller mass, behave differently from protons, alpha particles, and low-Z charged particles. Two quantitative parameters used to describe inelastic interactions of charged particles as they slow down in matter are stopping power and range. The total mass stopping power, $S/p$, is defined by the ICRU [10] as the quotient of $dE$ by $\rho dl$, where $dE$ is the energy lost by a charged particle in traversing a distance $dl$ in the material of density $\rho$. For energies for which the nuclear
interactions can be neglected, the total mass stopping power can be represented as the sum of an electronic (ionization and excitation) term and a radiative (bremsstrahlung) term as follows:

$$\frac{S}{\rho} = \frac{1}{\rho} \frac{dE}{dl}_{\text{elec}} + \frac{1}{\rho} \frac{dE}{dl}_{\text{rad}}$$  \hspace{1cm} (65.16)

Figure 65.8 illustrates the contributions of the electronic term and the radiative term to the total mass stopping power for electrons in lead and water over the energy range from $10^{-2}$ MeV to $10^3$ MeV. For alpha particles, the radiative term can be neglected, but the nuclear interactions cannot. The nuclear interactions are pronounced at lower energies, while at higher energies the inelastic collision process dominates. This is illustrated in Figure 65.9 for alpha-particle interactions in lead and water.

The range of a charged particle of a given energy in a material is an important parameter in designing detectors and shielding materials. In general, a charged particle does not travel in a straight line as it slows down. However, the total rectified path length traveled by the charged particle, called the mean range, is given by

$$r_0 = \frac{E}{\int_0^S dE}$$  \hspace{1cm} (65.17)

where $E$ = incident electron energy. The range as given in Equation 65.17 has units of g cm$^{-2}$. Range in water and lead as a function of incident particle energy for electrons and for alpha particles is given in Figures 65.10 and 65.11, respectively.

**Neutron Interactions**

Since neutrons are uncharged, they can travel some distance in matter before they interact. This interaction is normally a "nuclear reaction" in which the neutron is absorbed, scattered, or produces a nuclear reaction. The probability of each of these interactions occurring is described by the capture, scatter, and nuclear reaction cross sections. Secondary particles produced by neutrons are usually high-energy charged

![FIGURE 65.8 Stopping power for electrons in water and lead as a function of electron energy [18].](image)
particles that are stopped in short distances in the stopping material. Neutrons from nuclear reactions normally start with energies of a few MeV. They are moderated by collisions with atomic nuclei until they experience a capture process. Capture cross sections for a given elemental stopping material exhibit resonances characteristic of specific nuclear excited states. The total neutron cross section of carbon as a function of neutron energy is shown in Figure 65.12 [20]. The structure in the cross section is the result of resonances in the compound nucleus formed by neutron interaction with $^{12}$C. The intensity of a neutron beam in an absorber will decrease exponentially (analogous to a photon beam) with absorber thickness. The attenuation coefficient will include the scatter and capture components.

FIGURE 65.9 Stopping power for alpha particles in water and lead as a function of alpha-particle energy [19]

FIGURE 65.10 Range-energy curves for electrons in water and lead [18].
Radioactivity Measurements

Measurements of electromagnetic radiations and charged particles are discussed in Chapters 66 through 69. However, there are certain classes of instruments that are widely used for the measurement of radioactivity. Three examples will be dealt with here: alpha- and beta-particle liquid-scintillation spectrometers, high-purity germanium (HPGe) gamma-ray spectrometers, and gamma-ray dose calibrators.
Most liquid-scintillation spectrometers operate with two phototubes that view a cylindrical vial containing the radionuclide intimately mixed with an organic liquid scintillator [21, 22]. The radiations emitted during radioactive decay interact in the scintillator to produce light pulses that strike the photocathodes of the phototubes. The magnitude of the light pulse depends on the energy deposited by the radiation and on chemical and optical quenching processes [21]. The scintillation yield for high energy electrons (low dE/dx) for the best organic scintillators does not exceed 5 percent. That is, 5 percent of the deposited energy is emitted as photons in the near ultraviolet (~400 nm wavelength) and the remaining 95 percent is lost to radiationless transitions in the organic molecules. In real samples, this photon yield is reduced further through chemical processes (electron scavengers), and optical losses (colored samples, mismatches at vial interfaces, etc.). The counting efficiency for the two phototubes in coincidence is defined as the ratio of the counting rate to the activity. The counting efficiency approaches unity for beta particles with energies exceeding 20 keV [23]. For alpha particles, the efficiency is essentially unity (although the magnitude of the light pulse for alpha particles is less than that for beta particles due to the nature of the interactions of the particles with the organic scintillator). The counting systems are calibrated using standard solutions of known activity [22]. Since the pulse height is largely proportional to the energy of the incident particle, the signal from the counting system can be sorted according to pulse height in a multichannel analyzer (MCA). The pulse height spectra for a mixture of alpha-particle emitters is shown in Figure 65.13 [24]. In practice one obtains the area under the peak for a given radionuclide and divides by time to get the counting rate $N_a$. The activity $A_0$ is given by $N_a/e_c$, where $e_c$ is the coincidence counting efficiency.

The activity of mixtures of gamma-ray emitters is needed at many stages in the nuclear fuel cycle. For example, in measurements of environmental radioactivity, a gamma-ray spectrometer allows rapid determination of many fission and activation product nuclides in the presence of naturally occurring radioactivity. Both NaI(Tl) scintillation detectors and HPGe semiconductors are used for this purpose, and their design and operation are covered in Chapter 66. Gamma-ray spectra for a mixture of radionuclides with a semiconductor detector are shown in Figure 65.14 [22]. The detectors are calibrated using radioactivity standard sources prepared by the National Institute of Standards and Technology or one of the commercial secondary standards suppliers. A photopeak efficiency curve for a HPGe detector is shown in Figure 65.15.

![Figure 65.13](image-url)  
Liquid scintillation spectrum of mixture of alpha-particle-emitting radionuclides [24].
FIGURE 65.14 Gamma-ray spectrum for a solution standard of mixed radionuclides obtained with a Ge(Li) semiconductor detector [22].

FIGURE 65.15 Photopeak efficiency as a function of energy for a 90 cm$^3$ HPGe detector for a mixed radionuclide gamma-ray standard of the type listed in Table 65.5. A 5 mL solution source was positioned at 10 cm from the side of a p-type semiconductor [25].
Single radionuclides are widely used in many applications in health sciences. In nuclear medicine most samples are assayed in reentrant dose calibrators, which are essentially ionization chambers. In this counting geometry the sample is placed inside a well detector which is normally a sealed, pressurized argon gas, ionization chamber (See, for example, Figure 65.16). The photons emitted from the sample traverse the inner wall of the chamber and cause ionization events in the counting gas. The chambers typically operate at a few atmospheres pressure at a bias voltage of 600 to 1000 V. The charge created is subsequently collected at the anode. These chambers are designed to assay large amounts of activity such that the current from the device in picoamperes is proportional to the activity in megabecquerels. For a given radionuclide, the manufacturer can establish calibration factors for specific radionuclides in order to convert the current response of the chamber to a unit activity (pA MBq⁻¹). A dose calibrator response curve for gamma-ray emitters is shown in Figure 65.17 [26].

Radioactivity was first discovered by Henry Becquerel in 1896 when he noticed that photographic plates became fogged after exposure to uranium atoms. In addition to uranium nuclei, many other naturally occurring and man-made isotopes are known to be radioactive and decay by emitting uncharged particles (gamma rays and neutrons) and charged particles (alpha or beta particles) from their nuclei. Over the past few decades, there has been a growing need for monitoring, locating, and imaging radioactive sources in a wide variety of medical, environmental, industrial, space, scientific, and national security applications. Many of the applications rely on the use of commercially available radiation detectors, whereas others require development of new detectors to meet system requirements related to sensitivity, power, size, portability, ruggedness, maintenance, radiation hardness, and energy resolution.

The signals generated by a radiation-sensing system depend on (a) the mechanisms in which the incident radiation interacts with the detector material and (b) the scheme used to readout the interaction. In general, there are three types of radiation sensors in use today: gas-filled detectors, scintillation devices, and semiconductor detectors. The types of radiation sensors can also be divided into two groups according to whether they can measure the energy of the emitted gamma-rays, X-rays, or charged particles. Whenever an energy-resolving capability is desired, a large number of information carriers must be generated for each absorbed pulse to reduce the statistical limit on energy resolution. This is best accomplished by use of semiconductor detectors, although some spectral information can be achieved through the use of scintillators and gas-filled detectors.

The typical unit of measure of radioactivity is the becquerel (Bq), which is defined as the rate of one disintegration per second of a decaying isotope. Another common measure of radioactivity is the curie, which can be obtained by multiplying the becquerel by $3.7 \times 10^{10}$.
This chapter is divided into sections on gaseous, scintillation, and semiconductor detectors. Separate sections describing semiconductor detectors that must be cooled to cryogenic temperatures for operation and those capable of operation at ambient temperatures are presented. There are several texts devoted to the subject of radiation detection [1–7], and the reader is directed to these books for more detailed information on the principles of detector operation, device performance, problems limiting detector performance, areas of current research and development, and applications.

### 66.1 Gaseous Detectors

Ionization in a gas resulting from the interaction of X and gamma radiation is the basis for a wide variety of radiation detectors. The versatility of gas phase detection arises from the great flexibility in detector sizes and shapes that can be produced, their relatively low production cost, and particularly, the ability to perform a multitude of measurement tasks. Gas detectors can be separated into three distinct types: ionization chambers, Geiger-Müller counters (tubes), and proportional counters with numerous variations of each type. All utilize the ions and electrons created by the interaction of an incident photon with the detector gas, directly or indirectly, to produce an output signal. They differ in the characteristics of the electric field and nature of the output signal.

Ionization chambers can be operated in either a current mode or pulsed mode, although the current mode is more common. They operate by collecting (with an applied electric field) all the charge generated by the original ionizing event and differ in this way from both proportional and Geiger-Müller counters. The latter, normally operated in a pulsed mode, have output signals that result from amplification of the original ion pairs by gas multiplication processes.

### General Operating Principles

Fundamental to the operation of gas detectors is the generation of electron-ion pairs and their movement through the surrounding gas under the influence of an applied electric field. It is convenient to summarize basic features of these processes before turning to specific detector designs.

#### \( W \) Values

The energy \( (W) \) required to produce an electron-ion pair in a gas depends on the gas, the type of radiation (and its energy). \( W \) values for fast electrons in common filling gases range from 26.4 eV per ion pair in argon to 41.3 eV per ion pair in helium. The presence of nonionizing energy loss processes accounts for the \( W \) values greatly in excess of the ionization energy. Fluctuations in the number of pairs produced from photons of the same energy are of significance in pulse-mode operation. The variance is generally less than expected based on Poisson statistics and is accounted for by an empirical constant, the Fano factor (typically 0.1 to 0.2).

#### Charge Transport

The motion of free electrons and ions in the gas under the influence of the electric field \( (E) \) is quite different. The drift velocity \( (v) \) of the more massive ions is a linear function of \( E/p \) where \( p \) is the gas pressure. It can be expressed as

\[

v = \frac{\mu E}{p}

\] (66.1)

The proportionally constant \( \mu \) is the mobility, which depends on the type of gas and the charge of the ion. Values are typically in the region of 1000 cm\(^2\)/V-s/mm Hg. The electron mobility is normally about 1000 times ion values; the electron drift velocity is not linear in \( E/p \) [8].
Electric Field Effects

The amplitude of a pulse resulting from the interaction of a photon with the wall or fill gas depends strongly on the voltage applied to the detector and serves to distinguish the three detector types. A plot of pulse amplitude as a function of applied voltage is shown in Figure 66.1. The plateau following the initial steep segment is the region of ion chamber operation. It is a region where the electric field is sufficient to reduce recombination of the original pairs to an acceptable value and further voltage increases yield no more charge (as it has all been collected) and ion saturation is established. Assuming complete charge collection, the output current accurately represents the rate ion pairs are being produced. This is the basis for ionization chamber operation.

The rapidly rising portion following the plateau marks the onset of gas multiplication (the initial electrons can acquire enough energy between collisions to generate further ionization). In the initial segment, the multiplication process is linear; that is, the charge collected is proportional to the number of original ion pairs. This is the defining characteristic of proportional counter operation. The proportionality eventually is ended at higher voltages by space charge effects caused by positive ions.

At yet higher voltages, the space charge becomes sufficient to reduce the electric field below the multiplication threshold and no further multiplication takes place. Thus, a condition is reached where the same number of positive ions are produced for all initial ion-pair populations, and the pulse amplitude is independent of the initial conditions. This characterizes Geiger-Müller counter operation.

Further details on the operation of these devices may be found in texts by Knoll [1], Price [9], Attix and Roesch [10], and Tait [11]. The monograph by Rossi and Staub [2] contains a lengthy discussion of ionization chambers together with data on the physics of the transport process.

Ionization Chambers

Ionization chambers have been designed for numerous X- and gamma-ray measurement applications. They are frequently employed in radiation survey instruments. They are found in parallel plate, cylin-
drical, and spherical geometries. Essential features of their design can be found in the parallel plate chamber shown schematically in Figure 66.2. The design shown contains an optional guard ring that helps to define the active volume of the chamber. The ring is normally maintained near the collector electrode potential. (Guard rings are also employed in very low current designs to reduce leakage current.) Because the current for the ionization chamber is low, typically 1 nA or less, considerable care must taken with the insulators to minimize leakage currents.¹

Because of the low output current, special care must be taken with the readout system. Both dc and dynamic-capacitor types are used. Only electrometers of the highest quality should be used. Dynamic-capacitor (or vibrating-reed) varieties provide more stable operation. They are normally the choice for very low current applications.

Several special-purpose ion chambers are notable. The “free air” chamber, a parallel-plate variant, is valued for accurate gamma ray exposure measurements, particularly when absolute measurements are required. This is achieved by collimation of the incoming gamma flux and by an internal design that ensures compensation for ionization produced outside the sensitive volume by secondary electrons. These chambers are limited to energies below about 100 keV, however. Cavity ionization chambers are widely used for dosimetry purpose. To function in this manner, it is necessary that they be designed to meet the requirement of the Bragg-Gray principle [12]. This states that the absorbed dose in a medium can be determined from the ionization produced in a small gas-filled cavity in the medium. The cavity dimension must be small compared to the range of the ionizing particles generated in the material so that the particle flux is essentially unperturbed. Of particular interest for health physics applications are

¹Note also that ionizing radiation can cause both permanent and transient resistivity losses in insulating materials and should be considered in high-flux or high-fluence applications.
tissue equivalent chambers where the wall material is a plastic that closely simulates the absorption properties of tissue.

**Proportional Counters**

Proportional counters utilize gas multiplication to amplify the charge of the initial ion pair population and have the important characteristic that the charge associated with the amplified pulse is proportional to the ion pairs produced initially. They are normally operated in a pulse mode. They can be operated sealed or in a gas flow mode. The sealed style is most common for X- and gamma-ray applications. While they are found in a number of geometries, cylindrical is the most common shape. A typical cylindrical design is shown in Figure 66.3. This relatively simple design features a central wire that is maintained at high voltage and a surrounding metal container that serves as the cathode. The electric field in this geometry is given by

\[ E(r) = \frac{V}{r} \ln \left( \frac{b}{a} \right) \]  

where \( V \) = anode-cathode voltage, \( a \) = anode wire radius, and \( b \) = inner radius of the cathode.

It should be noted that \( E(r) \) depends on the diameter of the anode wire, allowing the threshold electric field needed for multiplication to be obtained at relatively modest voltages. The multiplication process is confined to a small volume surrounding the anode where the field exceeds the multiplication threshold. The characteristics of several common counting gases are given in Table 66.1.

**FIGURE 66.3** Schematic diagram of cylindrical proportional counter.
Proportional counters can be used for both photon and particle measurements. In photon applications they are particularly valued for spectroscopy in the low energy X-ray region. Their energy resolution and detection efficiency is generally inferior to semiconductor detectors such as lithium-drifted silicon or mercuric iodide but they offer large surface areas, reliable operation, and low cost. The energy resolution $\Delta E$ for given gas mixture for a specific photon energy can be estimated from the statistical limit given by

$$\Delta E = 2.35 \left[ \frac{W(F + \beta)}{E} \right]^{1/2}$$  \hspace{1cm} (66.3)

where $F = $ Fano Factor, $\beta = $ variance factor (typically about 0.5) \cite{1}, $E = $ energy in eV, and $W = $ energy in eV required to produce an ion pair.

Energy resolution for a proportional counter at 5.9 keV can be expected to be on the order of 10 percent (Table 66.1).

**Geiger-Müller Counters**

Geiger-Müller counters (more commonly known as G-M counters or tubes) remain among the most widely used means of detecting X and gamma radiation. They have high sensitivity, are rugged, and offer low cost. Also of importance is the large amplitude of the output pulse (several volts, typically), which greatly simplifies the readout. Because of these factors, they are the detectors of choice for a variety of commercial gamma survey instruments. Like proportional counters, they utilize gas amplification to generate an output pulse, although here the output is independent of the initial number of ion pairs. They are counters only and not applicable to spectroscopy. A G-M counter with typical readout is shown schematically in Figure 66.4.

G-M counters typically use a noble gas filling, most frequently argon or helium. The gas pressure is normally in the region of a few tenths of an atmosphere. At this pressure, a typical counter would require about 1000 V.

The process that terminates multiplication in a G-M counter has important counting implications. The positive ions space charge and resultant subthreshold electric field (for gas multiplication) persist for some time after the discharge is terminated. As a result, there is an interval following each pulse when pulses from subsequent input gamma rays are not produced or have less than full amplitude. This is

![Image of a G-M counter circuit](https://example.com/GMcounter.png)

**FIGURE 66.4** Typical counting circuit using a G-M tube. $C_1$ represents the combined tube and wiring capacitance, $C_2$ is a blocking capacitor that isolates the high voltage from the counter/scaler. The time constant of the circuit is $RC_1$. 

© 1999 by CRC Press LLC
illustrated in Figure 66.5. The period between a full-amplitude pulse and the next discharge of any size is the dead time of the G-M counter ($T_d$). The time from the initial full amplitude pulse until another full amplitude pulse can be produced is the recovery time. Dead times in G-M counters are on the order of 100 µs, with recovery time several times that. If the dead time is known and independent of count rate, the true count rate $R_t$ may be determined in most cases from the observed rate $R_o$ by the expression

$$R_t = \frac{R_o}{1 - R_o R_d} \quad (66.4)$$

**Availability**

Ionization chambers, Proportional counters, and Geiger-Müller counters are standard commercial products. They are available as stand-alone detectors requiring the user to supply ancillary electronics or as part of an instrument. Custom design devices are also available.

**Scintillation Detectors**

Scintillators, one of the oldest means of detecting gamma radiation, remain the method of choice for a multitude of counting and spectroscopy applications, particularly when counting efficiency rather than high-energy resolution is the primary objective. They are also widely used to record transient radiation events and in timing applications. While available in solid, liquid, and gas phases, solids and liquids are preferred for gamma-ray applications. Scintillators have the common property of converting energy absorbed from the incident gamma ray into visible or near visible light. The scintillation detector thus consists of a scintillator element, in which gamma ray energy is converted to optical photons, and some form of a photocell, normally a photomultiplier tube, to convert the optical photons into an electrical signal for processing by ancillary electronics.

Desired properties of a scintillator include high transparency to its own optical emission, efficient conversion of the absorbed gamma energy into optical output, short duration of the output, and output

![Figure 66.5 Illustration of dead time (Td) in a typical G-M counter.](image-url)
that is proportional to the amount of energy absorbed. Other useful properties include the ability to be produced in large sizes, ability to be machined, stable output over a wide range of environmental conditions, and efficient gamma-ray absorption.

**Scintillation Process**

The excess energy contained by the scintillator as a result of the gamma-ray absorption is dissipated largely through nonradiative processes and appears as heat. A small fraction decays radiatively and appears as visible and near visible light. That fraction of the absorbed energy converted to optical photons is referred to as the scintillation efficiency, which varies from <1 to ≈10 percent for the more efficient scintillators.

The optical emission originates from electronically excited atomic and molecular states. The emission is broadband, frequently exceeding 50 nm at the half-intensity points. Temporally, it is characterized by a very fast rise, followed by exponential decay. For most purposes, the light pulse can be adequately represented by

\[
I(t) = N \left( e^{-\frac{t}{\tau_R}} - e^{-\frac{t}{\tau_I}} \right)
\]

where \( I(t) \) is intensity at time \( t \), and \( N \) is related to the total number of scintillation photons. \( \tau_R \) is the time constant associated with the pulse rise time, and \( \tau_I \) is the time constant for decay. The time required for the intensity to fall to \( 1/e \) of the maximum value is the pulse decay time. Optical pulses from organic scintillators are often described by the full width of the pulse at the half maximum of intensity. Further details of the scintillation process can be found in the text by Knoll [1] and, in particular, the treatise by Birks [13].

**Scintillator Types**

As previously noted, the scintillation process is observed in solid, liquid, and gas phases, but gamma applications are limited mainly to solids and liquids. This brief discussion is confined to the most common solid and liquid phase scintillants that are applicable to gamma ray detection. A number of scintillators, including pure organic crystals and gas scintillators used primarily for charged particles, are not considered. Those remaining fall into inorganic and organic types.

**Inorganics**

The most important of this group are crystals of inorganic salts containing trace quantities of activators to enhance the emission. Because of their high atomic number, high density, and light output, they are valued for gamma spectroscopy. They are available commercially in a variety of standard forms, including right cylinders and parallelepipeds, and are readily machined to custom shapes. Ruggedness varies considerably among crystal types; care in packaging and use is required. Encapsulated crystals are available, but integrated units comprising a scintillator and photomultiplier are also available and often preferable.

The most widely used of this group is sodium iodide activated with thallium, NaI(Tl). NaI(Tl) has high light output and is generally the choice for scintillator-based spectroscopy systems. This material is hydroscopic and must be encapsulated. A typical pulse height spectrum from a NaI(Tl) photomultiplier combination is shown in Figure 66.6.

Also useful for spectrographic applications is cesium iodide, which is available with either a thallium or sodium activator. The optical output of CsI(Tl) is at substantially longer wavelengths than either NaI(Tl) or CsI(Na) and is well matched to the spectral response of silicon. This has been successfully exploited to produce small, rugged CsI(Tl)-Silicon PIN devices. A spectrum of Cs-137 obtained with a CsI(Tl)/PIN detector combination is shown in Figure 66.7. Exceptional resolution can be obtained when CsI(Tl) is used with a mercuric iodide photocell. With this combination resolution at 662 keV of better than 5 percent has been reported [14].

FIGURE 66.7 Energy spectrum of Cs-137 (662 keV) obtained with a CsI(Tl)/PIN combination. Specifications CsI(Tl): 1 cm × 2 cm × 2 cm; PIN: 1 cm × 2 cm.
Two unactivated inorganic crystals, barium fluoride (BaF$_2$) and bismuth germinate (Bi$_4$Ge$_3$O$_{12}$), warrant comment. Barium fluoride has a weak subnanosecond component in the ultraviolet that is useful for timing and the recording of fast transients. With proper attention to ultraviolet transmission and photocell response requirements, gamma spectra can be obtained. Bismuth germinate has lower light output than either CsI or NaI and inferior energy resolution. However, because of its high density (7.1 g/cm$^3$) and the high atomic number (83) of bismuth, it is a good choice when high counting efficiency per unit volume rather than energy resolution is required.

Organics
Organic scintillators are available in both solid and liquid form. This group is characterized by very fast rise times (often subnanosecond) and decay times of a few nanoseconds. Their scintillation efficiency is about one-third that of the more efficient inorganics, however. Because of the low atomic number, photoelectric absorption is not significant. As a result gamma spectra consist mainly of a Compton continuum with, in large samples, a distinct Compton edge. Because of the absence of a photopeak, they are not well suited for spectroscopy applications. (High-Z additives such as tin or lead have been shown to enhance the photoelectric response but sometimes at the cost of light output.) They are particularly well suited for counting applications when very large detector volumes are required or for wide bandwidth measurements of fast transients. Because of the large number of available fluorescent organic compounds, organic scintillators are much more easily tailored to meet emission wavelength and decay time requirements than inorganics. The liquids typically consist of one or more fluorescent organic compounds dissolved in an aromatic solvent. A large number of formulations are commercially available. They can be obtained in sealed vessels suitable for mounting on a photomultiplier or as part of integrated scintillator–photomultiplier combination.

Solid organic solutions or plastic scintillator are prepared by dissolving fluorescent compounds in monomers of styrene or vinyl toluene, which then are polymerized. Like liquid organics, several different solutes can be used to achieve the desired wavelength and efficiency. Slabs of plastic scintillator several meters in length can be prepared in this manner. Alternatively, custom shapes can be either cast directly or machined.

Characteristics of several representative scintillators are shown in Table 66.2.

66.2 Germanium Detectors
High-purity germanium (HPGe) detectors are widely used for gamma-ray spectroscopy due to their combination of efficient absorption and high energy resolution. Figure 66.8 shows the cross sections of germanium and silicon for photoelectric absorption, Compton scattering, and absorption by electron–positron pair production in several materials used for solid-state nuclear rations detectors. Attenuation is significantly stronger in germanium than in silicon. Over much of the gamma spectrum, the dominant
interaction is Compton scattering. However, it is principally the stronger photoelectric absorption in germanium that makes it more suitable than silicon for gamma-ray spectroscopy. In the typical size germanium detector, a gamma ray may be scattered several times before it is photoelectrically absorbed. Thus, the energy of the gamma ray is primarily transmitted directly to a small number of electrons. These energetic electrons in turn interact with electrons in the valence bands to create mobile pairs of electrons and holes. In a detector with sufficiently large volume, the average number of electron-hole pairs \(N\) produced by an absorbed gamma-ray of energy \(E\) becomes independent of the details of the initial reaction path and varies linearly with \(E\) as follows:

\[
N = \frac{E}{\varepsilon} \quad (66.6)
\]

This relationship is more broadly valid and is the foundation of energy spectroscopy of gamma rays using semiconductors, gases, and cryogenic liquids (\(\varepsilon\) depending on the material). While \(\varepsilon\) is independent of the gamma-ray energy (and is also virtually the same for energy deposited by charged particles), \(\varepsilon\) in germanium does increase slightly with decreasing temperature, as does the energy gap. At 77 K, \(\varepsilon\) is 2.96 eV, and the energy gap is 0.72 eV.
Practical exploitation of Equation 66.6 depends on electronically detecting the motion of the ionized charge in an electric field. The signal-to-noise ratio is improved by reducing current flow in the detector from other mechanisms. In germanium, this is achieved by producing a rectifying and a blocking contact and by cooling to about 100 K. For a planar detector, a slice of high-purity germanium is diffused with the donor lithium on one side, forming a strongly $n$-type layer. The opposite side is implanted with the acceptor boron, forming a $p^+$ layer. When voltage is properly applied, the electric field direction prevents the majority carriers in the contact regions from being injected across the device. As the voltage is applied, a region depleted of holes will advance into the slice from the $n^+$ contact if the slice is $p$-type. If the slice is $n$-type, a region depleted of electrons will advance from the $p^+$ contact. At the depletion voltage $V_d$, the depletion region reaches the opposite contact. For germanium,

$$V_d = 565V \times \frac{N_e}{10^{10} \text{cm}^{-3}} \times \frac{d^2}{\text{cm}^2}$$

(66.7)

$N_e$ is the net charge density in the depleted or active region of the detector, and $d$ is the thickness of this region. This is a key relationship in high-purity germanium technology, as it quantifies the effect of the residual impurity concentration on device size and depletion voltage. Techniques to grow germanium pure enough for gamma detectors were pioneered by Hall [15] and the detector group at Lawrence Berkeley Laboratory (Haller, Hansen, and Goulding [16]), based on purification methods of Pfann [17] and crystal-growing techniques developed by Teal and Little [18] to produce crystals for germanium transistors.

**Leakage Current**

Germanium detectors need to be cooled to reduce leakage current. There are several potential sources of leakage current, including

- Diffusion of minority carriers from either doped contact into the depletion region
- Thermal generation of carriers at either bulk or surface defects in the depletion region
- Electrical breakdown at points where the electric field is concentrated due to irregularities in the contact geometry, large-scale inhomogeneities in the bulk, or surface states.

Current will also be generated if the detector is not shielded from room-temperature infrared radiation. Background nuclear radiation from materials near the detector and cosmic radiation also generate leakage current.

Germanium detectors are typically liquid-nitrogen cooled and operated between 85 K and 100 K. In this temperature range, leakage current is typically less than 40 pA in “good” detectors and is not a significant contributor to system noise (400 to 900 eV). Leakage current increases with temperature and eventually becomes the predominate noise component. Pehl, Haller, and Cordi [19] reported a leakage current driven system noise of 2 keV at 150 K and 7 keV at 170 K for an 8 cm$^3$ planar detector. These authors also reported that, above about 120 K, the leakage current had an activation energy of approximately one-half the bandgap and attributed this to generation at mid-gap surface states. Below 120 K, the temperature dependence was milder.

A typical detector/cryostat configuration is shown in Figure 66.9. The detector resides in an evacuated cryostat and is cooled by means of a copper rod inserted into a liquid-nitrogen dewar. The first stage of amplification is an FET, also cooled, positioned nearby the detector. Mechanical fixturing is designed to stabilize the detector and the mechanisms for contacting it, to provide a cooling path from the detector to liquid nitrogen, and to electrically insulate the high-voltage contact.

A variety of detector geometries are shown in Figure 66.10. These different electrode configurations allow efficiency and energy resolution to be optimized for different gamma-ray energies and applications. For example, the detector in Figure 66.10(c) minimizes noise by the lower capacitance of its electrode.
configuration at the expense of the reduced stopping power. Thus, this detector would be more suitable for lower-energy gamma rays.

**Coaxial Detectors**

The detector type shown in Figures 66.9 and 66.10(e) has a closed-end coaxial geometry. Nearly all of the largest-volume (active volumes of 100 cm$^3$ to 800 cm$^3$) HPGe detectors are of this type. This electrode geometry reduces both capacitance and depletion voltage with respect to a planar detector of the same volume. This latter benefit relaxes the constraint on material purity. In addition, charge collection distances are shortened, and the uncontacted surface area, frequently troublesome in processing, is reduced. Also, the HPGe is grown by the Czochralski technique and is therefore nearly cylindrical, even before machining. It is important, however, to note that the reduction in depletion voltage is realized only when the device is contacted so that it depletes from the outer contact to the inner contact. Thus,
$p$-type HPGe to be fabricated into a coaxial detector is lithium diffused on the outer diameter and, in the case of $n$-type HPGe, the outer diameter is boron implanted. The boron-implanted contact (depth approximately 0.2 $\mu$m) is thinner than the lithium-diffused contact (depth approximately 750 $\mu$m), so the $n$-type coaxial detector can detect lower-energy radiation and is usually built with a beryllium window in the aluminum end cap to take full advantage of this feature. The difference in the range of use is illustrated in Figure 66.11. The geometric asymmetry of the

$FIGURE\ 66.10$ Schematic cross section and electrostatic field distribution in high-purity germanium detectors. The dark line represents the $p$-$n$ junction: (a) true planar, (b) grooved planar, (c) low capacity planar, (d) truncated coaxial, (e) closed-end coaxial, and (f) well geometry.

$FIGURE\ 66.11$ Relative absorption efficiencies for typical $n$- and $p$-type detectors. (Darken and Cox, 1993, reprinted with permission of Oxford Instruments, Inc.)
contacting electrodes in the coaxial detector makes charge collection more dependent on the carriers (electrons or holes) traversing to the inner contact. As more gamma rays are absorbed near the outer contact, the carriers traversing to the inner contact must travel on average a longer distance. Also, charge traversal near the inner contact is particularly effective in inducing current in the external circuit [20]. Thus, the \( p \)-type coaxial detector with positive bias on the outer electrode is more sensitive to hole collection, and the \( n \)-type coaxial detector with negative bias on the outer electrode is more sensitive to electron collection. This is a crucial consideration in applications where the hole collection is going to be degraded during use by exposure to fast neutrons or other damaging radiation. The superior neutron damage resistance of the electrode biasing polarity on \( n \)-type coaxial detectors was demonstrated by Pehl et al [21].

A typical gamma-ray spectrum of a Co\(^{60} \) source taken with a coaxial HPGe detector is shown in Figure 66.12. The salient features are the full-energy peaks at 1.17 MeV and at 1.33 MeV, and the lower energy plateaus due to incomplete energy absorption of Compton-scattered gamma rays. The peak-to-Compton ratio [22] is generally 40 to 100, depending on the size and quality of the detector. The 1.33 MeV peak is shown separately in Figure 66.13. The energy resolution measured as the full width at half the peak maximum (FWHM) for typical coaxial germanium detectors is between 1.6 and 2.1 keV for 1.33 MeV gamma rays, again depending on the size and quality of the detector. The variance in the peak \( L^2 \) (FWHM \( = 2.35 \times L \), \( L \) being the standard deviation for a Gaussian distribution) can be divided into three additive components: the electronic noise component \( L_N^2 \), a component reflecting the variance in the number of electron-hole pairs created \( L_F^2 \), and a component due to incomplete charge collection \( L_T^2 \).

\[
L^2 = L_N^2 + L_F^2 + L_T^2
\]  
\[
L_F^2 = \xi EF
\]

**Figure 66.12** A \(^{60}\)Co spectrum collected with a 15% \( p \)-type detector showing typical features of germanium detector spectrum.
\[ F < 1 \] implies that electron-hole pair creation events are not uncorrelated. \( L_T^2 \) is usually dominated by the trapping of electrons and holes at defect sites. However, shorter electronic shaping times, lower electric fields, and larger detectors accentuate ballistic deficit (loss of collected charge in the external electronics due to the finite traversal time of the electrons and holes across the detector). \( L_N^2 \) is independent of gamma ray \( E \) and is the dominant resolution limiting factor at low energies. \( L_T^2 \) depends linearly on \( E \) and, for a coaxial detector, usually dominates \( L_N^2 \) for \( E \) over a few hundred keV. The energy dependence of \( L_T^2 \) is not given simply from first principles for an arbitrary trap distribution, but an \( E^2 \) dependence seems to fit under many circumstances. Thus, at high enough \( E \), \( L_T^2 \) is expected to be the largest component. For “good” detectors at 1.33 MeV, however, \( L_N^2 \) is always smaller than \( L_T^2 \). In addition, the magnitude of \( L_T^2 \) is variable enough between detectors that it distinguishes between acceptable, very good, and excellent detectors. \( L_T^2 \) is usually also the only component of resolution drawn from a nongaussian distribution and is thus responsible for any low-energy tailing of the peak.

**X-Ray Detection**

Both silicon and germanium detectors are used in low noise systems for the detection of fluorescent X-rays produced by electron beams (usually in an electron microscope) or X-rays (XRF). For both materials the detector is liquid-nitrogen cooled to reduce leakage current, and small volume devices [Figure 66.10(b), typically 10 mm² active area, and 3 mm depth] are used to decrease capacitance and therefore to further reduce electronic noise. Lithium-drifted silicon (SiLi) detectors were used first for these applications. Early germanium detectors displayed poor peak shape for X-ray energies just above the L absorption edges (attributed to diffusion against the field to the front contact by some electrons and their resulting loss to the photopeak [24]). However, as was first demonstrated by Cox et al., [25] this is not a fundamental problem but can be solved by the contacting technology. An X-ray spectrum taken with a HPGe detector is shown in Figure 66.14. Germanium has the advantages with respect to silicon of a smaller \( \epsilon \) (2.96 eV per pair versus 3.96 eV per pair at 77 K) for better energy resolution and a higher \( Z \) (32 versus 14) for better photoelectric absorption of higher-energy X-rays.
Current Status of HPGe Detector Technology
